connected with thiamine deficiency. Campbell and Russell (1941) could find a definite history of alcoholism in only 5 of 21 cases, and Spillane (1947) listed the following additional causes in his review of the literature: carcinoma of the stomach, pregnancy, toxæmia, pernicious anaemia, vomiting, diarrhoea and dietary deficiency. Very occasionally the condition has developed in association with anorexia nervosa (Ebels 1978; Handler & Perkin 1982), and it has been reported after a self-imposed 'hunger strike' in a paranoid patient (Pentland & Mawdsley 1982). Other causes have included prolonged intravenous feeding, renal dialysis, hyperemesis gravidarum (Bergin & Harvey 1992) and severe malnutrition in a chronic schizophrenic patient (Spittle & Parker 1993).

Rimalovski and Aronson (1966) reported a large post-mortem series and found that unequivocal evidence of alcoholism had been recorded in only 50% of patients. In most of the remainder the cause appeared to be carcinoma, especially of the oesophagus, or widespread tuberculosis. Lindboe and Løberg (1989) found that almost one-quarter of their post-mortem cases were non-alcoholics, this rising to 40% in active acute cases. Most of the non-alcoholic patients had suffered from severe cachexia due to a variety of underlying diseases. Nevertheless, in the largest series reported from the USA, Victor *et al.* (1971) found that all but two of their 245 cases were suffering from established alcoholism. They therefore still regarded Wernicke's encephalopathy as essentially a disease of alcoholics, at least in American urban society.

However, it seems that not all alcoholics are equally at risk. Many neglect their diets severely without developing an overt encephalopathy, whereas others may do so quite early in their alcoholic careers. A young alcoholic reported by Turner *et al.* (1989) presented with Wernicke's encephalopathy at the age of 18. Even from place to place the prevalence of Wernicke-Korsakoff syndrome appears to be remarkably uneven. First admissions to hospital with the condition have ranged from 65 per million population in Queensland, Australia to 8 per million in New York. At post-mortem it has emerged in 2.8% of persons in Western Australia, 2.2% in Cleveland, Ohio, 1.7% in New York, 0.8% in Oslo and 0.4% in France (Harper *et al.* 1989, 1995). No obvious correlations can be discerned with the per-capita consumptions of alcohol in these different countries. Numerous factors are likely to be involved: the beverage consumed, its thiamine content, patterns of drinking and patterns of dietary neglect.

However, there may be an important additional factor by way of personal susceptibility. Thiamine is important in relation to several key enzyme systems of the body and brain. It is first phosphorylated to TPP, which acts as a coenzyme, i.e. combines with proteins to form the effective enzyme system. This applies to enzymes such as transketolase, which is essential for the maintenance and synthesis of myelin, and the pyruvate dehydrogenase complex and α -ketoglutarate dehydrogenase complex, both of which play key roles in

brain glucose metabolism and energy production (Langlais 1995).

The question therefore arose whether persons vulnerable to thiamine deficiency could have an *inborn abnormality* by way of reduced affinity between TPP and the enzymes with which it must combine. Kaczmarek and Nixon (1983) and Pratt *et al.* (1985) showed that transketolase is heterogeneous, existing as a number of isoenzyme variants, some differing in their affinity for TPP (Greenwood *et al.* 1984). Certain variants have seemed to be specific to Korsakoff patients (Blass & Gibson 1977; Nixon 1984). Mukherjee *et al.* (1987) have presented some preliminary evidence which favours genetic transmission of reduced binding between TPP and transketolase in certain families. Other enzymes that depend on TPP for their proper functioning appear to have been little explored in relation to the syndrome. Pyruvate dehydrogenase and α -ketoglutarate dehydrogenase are just as essential as transketolase to brain cell survival, and all three have been shown to be greatly reduced in samples from the cerebellar vermis in patients with Wernicke-Korsakoff syndrome (Butterworth *et al.* 1993). Reductions in α -ketoglutarate dehydrogenase were particularly severe, and Butterworth *et al.* suggest that this could be the trigger for a series of metabolic events that culminate in neuronal death.

Wernicke's encephalopathy and beriberi

The relationship with beriberi proved more of an embarrassment, since the classic neuritic and cardiac forms of the disease seemed rarely to be associated with encephalopathy despite their dependence on thiamine deficiency. During the Second World War, however, experience in prisoner of war camps gave ample opportunity for observing relatively acute deficiency syndromes in large numbers of subjects. In epidemics of beriberi psychological changes were often found to be prominent, with irritability, depression and disturbance of memory (Cruickshank 1961).

More particularly, De Wardener and Lennox (1947) were able to report 52 typical cases of Wernicke's encephalopathy from a prisoner of war camp in Singapore, most of whom at the same time showed neuritic, cardiac or oedematous signs of beriberi. Their classic paper was based on records that spent two years of the war buried in a Siamese cemetery; it was entitled 'Cerebral beriberi (Wernicke's encephalopathy)', and effectively bridged the gap between the two conditions. Response to thiamine was generally excellent in this series. Gross examination of the brains in fatal cases confirmed pathological changes in the distribution typical of Wernicke's encephalopathy. The authors proposed that the encephalopathy appeared when particularly acute and severe thiamine depletion was superimposed on partial deficiency, whereas other forms of beriberi generally resulted from less severe and more prolonged lack of the vitamin. In almost all their cases the encephalopathy had set in when

some other factor, such as epidemic diarrhoea, had intensified the vitamin deficiency. The situation was thus analogous to that seen with nicotinic acid, where severe acute depletion produces profound evidence of cerebral dysfunction and more chronic deficiency leads to pellagra.

Clinical features

Victor *et al.*'s (1971, 1989) observations on 245 patients form the basis for much of the description that follows. Wernicke's encephalopathy typically declares itself abruptly, although sometimes it may be several days before the full picture is manifest. The commonest presenting features are mental confusion or staggering gait. The patient may also be aware of ocular abnormalities, with complaints of wavering vision or diplopia on looking to the side. This well-known triad of confusion, ataxia and ophthalmoplegia confers a highly characteristic stamp to the syndrome when it appears in full, but all parts are not always seen together. In an admittedly retrospective analysis of 97 autopsy-proven cases, Harper *et al.* (1986) found that the classic triad had been present in only 16%; 28% had shown two of the signs and 37% only one, but in 19% no feature of the triad was documented. A high index of suspicion is therefore necessary if the condition is not to be missed. Other features include prodromal anorexia, nausea and vomiting. A marked disorder of memory is frequently in evidence and has been insufficiently emphasised in most descriptions. Attention has also been called to lethargy and hypotension which, in the presence of an acute organic mental syndrome, may indicate Wernicke's encephalopathy despite the absence of other definitive signs (Cravioto *et al.* 1961). Rare presentations may be with hypothermia, stupor or coma (Kearsley & Musso 1980).

The age range is evenly distributed throughout adult life, with males affected approximately twice as often as females. This ratio is considerably lower than for alcoholism generally and may be partly a reflection of differences in patterns of drinking. The pattern which leads to Wernicke's encephalopathy appears to be steady drinking extending over months or years and coupled with inadequate intake of food. In Victor *et al.*'s (1971) series, delirium tremens or other withdrawal syndromes had occurred at some time in the past in 40% of cases, withdrawal fits in 10% and liver disease in 10%, indicating the general severity of alcohol abuse.

On examination, Victor *et al.* observed the following signs.

Ocular abnormalities were present in 96% of patients on initial examination. The commonest findings were nystagmus, sixth nerve palsies producing lateral rectus weakness, or some form of conjugate gaze paralysis. The pupils usually showed little more than sluggishness of reactions. Ocular signs can be remarkably evanescent, resolving speedily with treatment or even on feeding thiamine-containing foods. This no doubt accounts for the much lower prevalence

of ocular abnormalities reported in cases viewed retrospectively.

Ataxia was observed in 87% of patients who were testable, varying from inability to stand without support to minor difficulties with heel-toe walking. In contrast, intention tremor in the legs or arms was relatively rare.

Peripheral neuropathy was present in 82% of cases, usually confined to the legs. In addition to objective signs there were often subjective complaints of weakness, paraesthesiae and pain.

Serious malnutrition was evident in 84%. Common signs were redness or papillary atrophy of the tongue, cheilosis, angular stomatitis, telangiectases, and dryness and discoloration of the skin. Two-thirds of the patients showed evidence of liver disorder and one-quarter were bedridden when first seen. Overt signs of beriberi were rare but resting tachycardia and dyspnoea on effort were common.

Abstinence syndrome was found at inception in 13%, with epileptic fits, hallucinosis or delirium tremens.

Mental abnormalities were observed in 90% of patients, the rest presenting with ataxia and ophthalmoplegia but remaining lucid throughout. The commonest mental disturbance was a state of quiet global confusion, with disorientation, apathy and derangement of memory. Many were drowsy, sometimes falling asleep in mid-sentence, while others showed marked indifference and inattention to their surroundings. Against the prevailing view, however, almost all were readily rousable and impairment of consciousness was rarely profound or persistent.

In the typical case, spontaneous activity and speech were minimal, and remarks irrational and inconsistent. Grasp, awareness and responsiveness were markedly impaired. Misidentifications were extremely common and made without hesitation. Physical and mental fatigability was pronounced, and concentration was difficult for the simplest task. In contrast, a small proportion were alert, responsive and voluble, despite obvious confusion and defects of memory.

Evidence of delirium was sometimes seen, with perceptual distortions, vivid hallucinations, insomnia, agitation and autonomic overactivity. In a small number this amounted to frank delirium tremens, but was always evanescent and usually not severe. Hallucinations were rare in the remainder. Loosely knit delusions appeared occasionally and sometimes persisted for weeks after the confusion had cleared.

Assessment of memory was often difficult, but in testable cases a defect of memorising was discovered or else became evident as soon as the major confusion subsided. It was often hard to determine the point at which confusion of thought receded and the memory defect became the most prominent

abnormality, since the two usually blended imperceptibly in the course of the illness. In a small number (14%) a typical Korsakoff memory defect was clearly evident from the outset, being the most prominent mental abnormality at the time of initial examination.

Confabulation was common early in the disorder but was not found in every case. In those who showed it, moreover, it could not be elicited on every occasion. The origin could often be traced to confusion of thought or perceptual disorder, and it was sometimes hard to separate confabulations from misidentifications and misinterpretations. As the global confusion receded and memory defects became clearly established, the confabulation subsided and often amounted to translocations in time of genuine past experiences.

Investigations

Diffuse slowing was found on EEG in half of the patients tested by Victor *et al.* (1971). Sometimes, however, the tracings were entirely normal in marked and classic examples of the syndrome. More recent EEG evidence indicates that Wernicke's encephalopathy usually produces prominent generalized asynchronous slow waves and often also causes bisynchronous slow waves and a decrease of the alpha rhythm (Fisch 1999).

The CSF may be abnormal with mild elevation of protein.

In occasional examples, CT has shown symmetrical areas of decreased attenuation in the region of the thalamus (Escobar *et al.* 1983; McDowell & Le Blanc 1984). In the latter study the lesions were observed to improve after several weeks of treatment with thiamine. MRI can show such lesions more clearly, and may also identify atrophy of the mamillary bodies (Charness & DeLaPaz 1987; Bigler *et al.* 1989) or hyperintensities surrounding the third ventricle and aqueduct (Gallucci *et al.* 1990). Meyer *et al.* (1985) demonstrated reductions in both grey and white matter cerebral blood flow, which improves with treatment.

Course and response to treatment

The unique value of Victor *et al.*'s (1971, 1989) series was that a substantial proportion of the patients who survived the acute stage remained under close medical observation for many months or years thereafter. Altogether 17% died during the acute stage, one-quarter were followed for at least 2 months, and more than half were followed for 2–13 years. The long-term outcome with thiamine replacement was accordingly greatly clarified.

Sixth nerve palsies always recovered, often starting to resolve within hours though sometimes taking several days or weeks to disappear completely. Other ocular abnormalities responded similarly, with the exception of horizontal nystagmus which was a permanent residuum in two-thirds of the patients. Ataxia usually began to improve within the first week, but often took a month or two for maximum

resolution. In one-quarter of patients the ataxia showed no improvement whatever, and altogether more than half were left with permanent unsteadiness of some degree. Thus residual ataxia and nystagmus can sometimes be useful signs in pointing to the origin of an obscure chronic amnesic syndrome. Polyneuropathy improved only very slowly over several months, and diminution or absence of tendon reflexes was another common permanent sequel.

The global confusion always recovered in survivors, beginning usually within 2–3 weeks and clearing completely within 1–2 months. As the confusion receded the amnesic defects stood out more prominently. Of 186 patients followed for long enough to assess the presence or absence of the Korsakoff state, 84% developed the typical amnesic syndrome. The few who escaped had all shown relatively brief acute illnesses and had lost their confusion within a week. In addition the authors drew attention to the small but important group who presented with the Korsakoff amnesic defect from first contact along with ocular and ataxic signs (some 10% of the total), and their further very small group of nine cases (4%) who had apparently developed the amnesic syndrome without ophthalmoplegia or ataxia at any time (compare Cutting 1978).

Pathology

The pathological changes are remarkable for their predilection for certain circumscribed parts of the brain. Symmetrical lesions are found predominantly in the neighbourhood of the walls of the third ventricle, the periaqueductal region, the floor of the fourth ventricle, certain thalamic nuclei (including especially the paraventricular parts of the medial dorsal nuclei, the anteromedial nuclei and the pulvinar), the mamillary bodies, the terminal portions of the fornices, the brainstem, and the anterior lobe and superior vermis of the cerebellum. In contrast, obvious lesions are rarely seen in the cerebral cortex, corpus striatum, subthalamic and septal regions, cingulate gyri or hippocampal areas. However, Victor *et al.* (1971) found that convolutional atrophy was conspicuous enough to be remarked on in 27% of their cases who came to post-mortem.

Microscopically, the lesions tend to involve all neural elements – neurones, axis cylinders, blood vessels and glia – but with variability from case to case and from one location to another. In general, myelinated fibres tend to be affected more severely than the neurones themselves. Astrocytic and histiocytic proliferation is found in the areas of parenchymal loss. Proliferation of blood vessels and petechial haemorrhages may occur, but the latter may often represent terminal events.

The distribution of lesions is virtually identical in patients dying in the acute stages of Wernicke's encephalopathy and in patients who have shown a chronic Korsakoff syndrome, differing only in the chronicity of the glial and vascular reactions.

In seeking a correlation between symptoms and lesions, Victor *et al.* (1971) suggested that the ophthalmoplegias result from lesions in the third and sixth cranial nerve nuclei and adjacent tegmentum, nystagmus from lesions of the vestibular nuclei, and ataxia from lesions of the vestibular nuclei and the anterior lobes and vermis of the cerebellum. Amnesia in their material appeared to be particularly closely associated with lesions in the medial dorsal nuclei and pulvinar of the thalamus; mammillary lesions, which have traditionally been regarded as crucial for the development of amnesia, were less constant (Victor *et al.* 1971, 1989). More recent studies have disputed this view, arguing that the pathology specifically in the mammillary bodies, the mamillothalamic tract, or the principal anterior nuclei of the thalamus is critical to producing the persistent and severe anterograde memory deficit of the Korsakoff syndrome (Harding *et al.* 2000).

Subclinical Wernicke's encephalopathy

The foregoing description applies to patients who have come dramatically to medical attention on account of an acute disorder. However, it seems probable that milder variants may exist, or indeed that damage may sometimes develop surreptitiously in the Wernicke location without clear clinical indicators of the process (Lishman 1981). The evidence is somewhat indirect but the pointers towards it deserve careful consideration.

Cravioto *et al.* (1961) and Grunnet (1969) found patients with the classic lesion at post-mortem who had died without exhibiting Wernicke's classic signs. Comparison of patients dying in the 1930s and 1960s suggested that the clinical presentations had become less severe, perhaps as a result of the wider availability and prescription of vitamins. The lesions at post-mortem tended to be more circumscribed in the recent cases, and more often subacute or chronic in nature. Most significant of all, the condition could remain undiagnosed prior to death.

This last point has been strongly reinforced by Harper (1979, 1983). Over the course of 9 years in Perth, Australia, 131 cases of Wernicke's encephalopathy were diagnosed at post-mortem, representing almost 3% of all brains examined in the hospital or referred by the city coroner. Only 26 of these 131 cases had been suspected during life, despite the fact that most had been examined in teaching hospitals. The great majority of affected persons were known to be alcoholics, and several had died suddenly and unexpectedly. A considerable range was encountered in the acuteness or chronicity of the lesions, with the not uncommon conjunction of acute histological changes superimposed on chronic pathology within the same brain regions. Two-thirds showed chronic pathological changes alone.

Some alcoholics may therefore harbour covert undiagnosed pathology of the Wernicke type over a considerable period of time. Whether this evolves insidiously or in

stepwise fashion is unknown. It may sometimes represent the cumulative effects of repeated minor episodes of Wernicke's encephalopathy that have largely gone unnoticed at the time.

In favour of the idea is the noted resistance to treatment of many alcoholic Korsakoff states, even when thiamine is administered from the earliest stages. This contrasts with the gratifying responses observed, for example, in De Wardener and Lennox's (1947) nutritionally depleted prisoners of war. The alcoholics appear often to have acquired an entrenched structural pathology that may well have been evolving for some time. Those cases in which the Korsakoff syndrome develops insidiously, without an obvious Wernicke episode (see Chapter 2), could equally be explained on such a basis. It could conceivably be the case that covert pathology of this nature makes a contribution to the memory deficits encountered in alcoholics generally.

The issue is of potential therapeutic importance. If a substantial number of alcoholics develop a thiamine-dependent pathology well before it is clinically apparent, high-potency vitamin therapy should find wider prophylactic application. The feasibility and desirability of routinely supplementing alcoholic beverages with thiamine has indeed received consideration (Centerwall & Criqui 1978; Weinstein 1978; Bishai & Bozzetti 1986; Finlay-Jones 1986; Rouse & Armstrong 1988). Price *et al.* (1987) conclude that fortification of flour alone, as practised in the UK and USA, is insufficient for prophylaxis in problem drinkers. Reuler *et al.* (1985) estimate that the supplementation of alcoholic beverages in the USA would merely cost the consumer an additional 0.1 cent per litre of wine. The identification of persons at special genetic risk (see Wernicke's encephalopathy and alcoholism, earlier) could also prove to be important. However, these are matters to be clarified by future research.

Treatment

Wernicke's encephalopathy represents an acute medical emergency and warrants energetic treatment from the moment the diagnosis is made. Doses of thiamine as small as 2–3 mg can modify the ophthalmoplegias, but much larger doses are indicated to minimise the chance of disabling sequelae, particularly since associated hepatic disorder may interfere with utilisation of the vitamin. In view of the possibility of other concurrent vitamin deficiencies, Pabrinex is usually employed intravenously in place of thiamine alone. Intravenous infusion should always be carried out slowly over 10 minutes on account of the risk of anaphylactic reactions. Each injection of Pabrinex contains thiamine hydrochloride 250 mg, nicotinamide 160 mg, riboflavine 4 mg, pyridoxine hydrochloride 50 mg and ascorbic acid 500 mg. The duration of treatment is controversial, but should be for at least 5 days twice daily, followed by high-dose oral thiamine. In the occasional patient who seems refractory to thia-

mine replacement, determination of the serum magnesium level may be indicated. Traviesa (1974) showed that hypomagnesaemia impaired both the biochemical and clinical response to treatment. The syndrome of nicotinic acid deficiency encephalopathy (see under Wernicke's encephalopathy and beriberi, earlier) must also be kept in mind when response has been lacking or incomplete to the replacement of thiamine alone.

Other aspects of management must include attention to infection, dehydration or electrolyte imbalance as a result of vomiting. Signs of congestive cardiac failure should be treated. Disturbed behaviour, and particularly that due to coincident delirium tremens, will require appropriate sedation.

Oral vitamin supplements are usually continued for several weeks after the acute illness has resolved. In patients with enduring ataxia, polyneuritis or memory disturbance, high-potency vitamin injections should be pursued energetically as long as improvement is occurring.

Korsakoff's syndrome

The relationship between Wernicke's encephalopathy and Korsakoff's syndrome has gradually been clarified. Korsakoff gave the first comprehensive account of the amnesic syndrome that bears his name in 1887, shortly after Wernicke's description of his syndrome, but the close relationship between the two was not appreciated at the time.

All Korsakoff's cases had polyneuritis, which led him to propose the name 'psychosis polyneuritica'. The great majority of cases were reported in alcoholics and the cause was thought to be some toxic effect of alcohol. Shortly thereafter cases were reported without alcoholism or neuropathy in patients suffering from puerperal sepsis, typhoid or intestinal obstruction. By the 1930s other known causes included gastric carcinoma, intractable vomiting and severe dietary deficiency. Thiamine deficiency therefore came under suspicion as the common metabolic link. Bowman *et al.* (1939) tried the effect of parenteral thiamine and reported encouraging results; disorientation and confabulation responded in many cases, but the memory deficits were largely unaltered.

Meanwhile, evidence accumulated to suggest a clinical link between Wernicke's encephalopathy and Korsakoff's syndrome. Features of the two disorders were sometimes seen together, and the former was often noted to lead to the latter. De Wardener and Lennox's (1947) cases were again important here, showing clear evidence of memory deficits in association with ataxia and ophthalmoplegias. The acuteness of their cases also allowed the memory deficits to respond unequivocally to thiamine in many cases. The link between the two conditions was consolidated when the site of the cerebral lesions in Korsakoff's syndrome was clarified. Malamud and Skillicorn (1956) provided clear evidence that in patients dying with Korsakoff's syndrome the location of cerebral pathology appeared to be identical with that seen in

Wernicke's encephalopathy, the two merely differing in the acuteness or chronicity of the pathological process.

The amnesic syndrome can, of course, result from a variety of brain lesions that have nothing to do with thiamine deficiency but, where the nutritionally depleted subject is concerned, Wernicke's encephalopathy and Korsakoff's syndrome appear to be different facets of the same pathological process. Confirmation came from the clinicopathological study of Victor *et al.* (1971), published under the composite title *The Wernicke-Korsakoff syndrome*. Of 186 alcoholic patients who survived the acute illness and were observed for long enough to assess the development of amnesia, 84% developed a typical Korsakoff syndrome. Other cerebral pathology may make additional contributions to the fully developed picture, but lesions in the Wernicke distribution appeared to be fundamental to the amnesic deficits displayed.

Follow-up of the Korsakoff patients showed complete recovery in one-quarter, partial recovery in half, and no improvement whatever in the remainder (Victor *et al.* 1971). Complete recovery was observed even in some very severe examples, although detailed follow-up neuropsychological assessment was not presented. The onset of improvement was commonly delayed for several weeks or months, and once started sometimes continued for as long as 2 years.

In the chronic amnesic stage anterograde and retrograde amnesia are the dominant features, but continuing minor impairments of perceptual and cognitive function could usually be discerned by careful examination. The retrograde amnesia is usually of several years' duration, although with islands of preservation and without a sharply demarcated beginning. Confabulation is rarely encountered in the chronic stage (see Chapter 2).

Over recent years, the following have become evident.

- 1 The classic lesion at the base of the brain is often associated with more widespread cerebral pathology, including cortical shrinkage and ventricular dilatation. The contribution that this may make to certain aspects of the clinical picture warrants careful appraisal.
- 2 The rarity of fully fledged Korsakoff's syndrome as a residue of thiamine deficiency in non-alcoholics raises the possibility that a direct neurotoxic action of alcohol may play some part in the evolution of the condition.
- 3 There is evidence that Korsakoff's syndrome may be misdiagnosed to a considerable extent in clinical practice.

Neuroimaging findings and cortical pathology

Cortical pathology was widely described in the earlier literature before the diencephalic basal brain lesion came to be fully appreciated (Lishman 1981). Thereafter interest in cortical aspects showed a pronounced decline. However, neuroimaging studies have re-emphasised that supratentorial changes are common. Jacobson and Lishman (1990) compared 25 Korsakoff patients, gathered from hospitals around

London, with non-Korsakoff alcoholics of similar age. On CT the Korsakoff patients had wider third ventricles, as might have been expected from their diencephalic lesions, but also significantly larger lateral ventricles, sylvian fissures and interhemispheric fissures. The widening of the interhemispheric fissures, measured between the frontal lobes, was particularly marked and showed significant correlations with certain tests of frontal lobe function (Jacobson 1989). Shimamura *et al.* (1988) found atrophy in frontal sulcal and perisylvian areas on CT in comparison with normal controls, the frontal atrophy correlating with impairment on memory and other tests. Jernigan *et al.* (1991b), using MRI, showed greater grey matter losses in the medial temporal and orbitofrontal cortex when Korsakoff patients were compared with non-amnesic alcoholics. However, Colchester *et al.* (2001) showed statistically significant reduction in thalamic volume in 11 Korsakoff patients whereas medial temporal lobe volumes were relatively preserved, in contrast to patients with herpes encephalitis in whom atrophy was the other way around.

Further evidence of cortical involvement has come from functional brain imaging studies. Hunter *et al.* (1989) examined 10 Korsakoff patients with hexamethylpropyleneamine oxine (HMPAO)-SPECT, revealing impaired blood flow in the frontal regions that correlated significantly with deficits on tests of memory and orientation. Kessler *et al.* (1984) showed that glucose metabolism, as measured by FDG-PET, was reduced overall by 20% in Korsakoff patients, with hypometabolism present in numerous cortical areas in addition to the thalamus and basal ganglia. However, Joyce *et al.* (1994) found that FDG-PET showed robust hypometabolism in only three regions, the anterior cingulate, posterior cingulate and precuneate areas, in comparison with normal controls. Reed *et al.* (2003), using quantified FDG-PET, showed significant hypometabolism in the thalamic, ventromedial frontal, and retrosplenial regions only. EEG studies in Korsakoff's syndrome have revealed mild or moderate generalized slow waves with only a few cases showing more prominent generalized slow waves (Fisch 1999).

A substantial cortical component to the pathology could be relevant to the wider cognitive deficits often detected in Korsakoff patients on detailed psychological testing, sometimes exceeding those in matched non-Korsakoff alcoholics (Jacobson *et al.* 1990). Various authors have demonstrated impairments on executive or frontal lobe tests in Korsakoff's patients (Janowsky *et al.* 1989; Joyce & Robbins 1991; Kopelman 1991). These impairments could also explain some of the striking clinical aspects of the syndrome, in particular apathy, lack of initiative and profound lack of insight that the majority of patients display. As discussed in Chapter 2, these are not inevitable concomitants of severe memory disorder, and can be entirely absent in amnesic syndromes of other aetiologies.

Neurotoxic action of alcohol in Korsakoff's syndrome

Thiamine replacement is not regularly effective in reversing the memory difficulties; and as Freund (1973) pointed out there is a remarkable lack of evidence that permanent memory disorder can follow thiamine deficiency unaccompanied by alcohol abuse. There have been occasional reports of a persistent Korsakoff syndrome following severe vomiting, malabsorption or prolonged intravenous feeding, but in a close examination of these Kopelman (1995) concludes that the evidence for a non-alcoholic nutritional cause must still be regarded as equivocal.

The inevitability of the link between an overt episode of Wernicke's encephalopathy and Korsakoff's syndrome may also be challenged on the basis of clinical experience. In many Korsakoff patients there is evidence of a pre-existing Wernicke encephalopathy, as reported by Victor *et al.* (1971), but in others no such history is forthcoming. Some patients appear to develop their amnesic difficulties insidiously (Cutting 1978), in the context of chronic continuing inebriation. Such patients would be under-represented in Victor *et al.*'s sample, since most of their patients were incepted as cases of Wernicke's encephalopathy then followed through to the Korsakovian development.

Thus while the relationship between thiamine deficiency and Wernicke's encephalopathy cannot be doubted, there is less clear-cut evidence to incriminate thiamine exclusively in the chronic Korsakoff state. A combination of alcohol neurotoxicity and avitaminosis may be necessary for the development of the fully fledged syndrome, as discussed in some detail by Lishman (1990). An alternative explanation is that in alcoholics thiamine deficiency may have been operative over a considerable period of time. In other words, alcoholism may tend to be associated with a 'subclinical' Wernicke pathology which, by the time it becomes overt, has led to fixed and irreversible structural changes.

Continuity hypothesis

It is interesting in this connection that certain continuities have been discerned between the memory deficits seen in Korsakoff's syndrome and those found in chronic alcoholics generally (Ryback 1971). Subtle but definite 'subclinical' memory deficits appear to be widespread in the alcoholic population, and these become more pronounced in alcoholics who complain of memory difficulties. In the latter the severity of the deficits can overlap to some degree with those seen in Korsakoff's syndrome. Continuities are also apparent in measures of third ventricular width as detected on CT. Either alcohol neurotoxicity or 'subclinical' thiamine deficiency could be the common link. Bowden (1990) has argued strongly for the latter, suggesting that in neuropsychological research a rigid distinction between Korsakoff and non-Korsakoff alcoholics should no longer be regarded as valid.

Diagnosis

The diagnosis of Korsakoff's syndrome requires clear evidence of a marked memory disorder along with relative preservation of other cognitive functions. Subtle deficits will often be revealed by special testing, as outlined under Psychological evidence, earlier, particularly with regard to visuo-perceptive functions and abstracting ability, but performance on standard intelligence tests should be substantially intact. This was well illustrated by Butters and Cermak's (1980) comparison of intelligence test scores (Wechsler Adult Intelligence Scale, WAIS) in a group of Korsakoff patients and a group of intact normal controls. The latter were carefully matched for age, socioeconomic class and educational background. With the sole exception of the digit-symbol subtest, no significant differences could be discerned in any aspect of test performance. In contrast, on measures such as the Wechsler Memory Scale, Butters and Cermak found that Korsakoff patients can generally be expected to score some 20–30 points below the expectation derived from their IQs.

In clinical practice such careful distinctions are not always observed. In a retrospective survey of 63 alcoholic patients admitted to the Maudsley Hospital, Cutting (1978) found 50 who had been labelled as having Korsakoff's syndrome and 13 as having alcoholic dementia. However, the Korsakoff patients proved to be heterogeneous. Those with a relatively acute onset mirrored the classic syndrome, with an isolated memory deficit and a poor prognosis as judged by capacity to resume independent existence. In contrast, 17 of the 50 differed from these acute cases in significant ways. Their symptoms had been several months in evolution, they tended to be older, females predominated over males, and some two-thirds showed improvement on follow-up. Psychological test profiles, where available, showed that the gradual-onset group, like the alcoholic demented, were impaired across a wider range of cognitive functions in addition to their memory problems. This suggested that several patients with more global cognitive impairments had been falsely labelled as suffering from Korsakoff's syndrome.

Jacobson and Lishman (1987) have also provided evidence of heterogeneity within the syndrome. They obtained separate indices of the severity of memory impairment and of 'generalised intellectual decline' in their sample of 38 chronic Korsakoff patients. The former was derived from the discrepancy between the WAIS IQ and the Wechsler Memory Quotient, the latter from the discrepancy between the WAIS IQ and the National Adult Reading Test which yields an approximate estimate of premorbid IQ. When the two indices were plotted against each other a marked scatter was apparent; some two-thirds of patients showed clear memory impairment with little fall from premorbid IQ (i.e. the classic Korsakoff pattern), others showed both mild memory and mild intellectual decline, whereas 10% showed little memory impairment but marked intellectual decline. Thus it appeared that there was an admixture of patients in the sample, with at one extreme a group that might more properly have been labelled as having more generalised cognitive impairment. Females featured disproportionately among those with generalised impairment as was the

case in Cutting's survey. Certain relationships could be discerned with CT scan parameters: widening of the third ventricle tended to be associated with more severe memory deficits, and widened interhemispheric fissures with greater fall from premorbid intellectual functioning.

It would seem therefore that patients with Korsakoff's syndrome show a variable degree of generalised impairment, particularly in executive or frontal lobe impairment but other deficits (e.g. in visuospatial function) can also occur. Certainly the label of Korsakoff's syndrome would appear to be more commonly applied in clinical practice than is strictly warranted.

Treatment

In the established chronic Korsakoff state treatment will often prove to be disappointing. Cutting (1978) reviews the differing reports in the literature, some finding no patients whatsoever with a significant response to thiamine and others obtaining improvement in up to 70% (Victor *et al.* 1971). Nevertheless, the possibility of occasional substantial improvement means that high-dose thiamine replacement must always be attempted by the parenteral route, and oral replacement should be pursued over many months if benefit continues to be observed.

Other nutritional disorders associated with alcoholism

Other disorders in alcoholics are suspected of being nutritional in origin, although the evidence is less complete. Of those considered below peripheral neuropathy is almost certainly due in part to vitamin deficiency, but here and in the others a direct toxic effect of alcohol may also be responsible.

Peripheral neuropathy

Alcoholic peripheral neuropathy may sometimes be symptomless and manifest only by loss of the ankle reflexes, but in most cases there are prominent complaints of sensory disturbance. It begins usually in the feet with numbness, pins and needles, burning sensations and pain. Sensory ataxia may be prominent. Weakness may progress ultimately to foot drop with wasting of the leg muscles. Cutaneous sensory loss is most marked peripherally in the hands and feet, and intense hyperaesthesia may be elicited on stroking the skin. The calf muscles are often very tender. Oedema of dependent parts may develop along with dystrophic changes of the skin and nails.

The condition often accompanies Wernicke's encephalopathy or Korsakoff's syndrome, and some 50% of patients with neuropathy show residua of these disorders. It may also present as an isolated abnormality, or in association with delirium tremens. The main cause appears to be deficiency of thiamine, although other deficiencies may be important as well. Pyridoxine and pantothenic acid deficiency can produce neuropathy and are likely to be involved in some alcoholics. A toxic role for alcohol itself, or other toxic

substances in alcoholic beverages, has been proposed, but slow recovery is usual with vitamin therapy even though drinking continues.

Cerebellar degeneration

Victor *et al.* (1959) have described a remarkably uniform cerebellar syndrome in alcoholics, with ataxia of stance and gait as the principal abnormalities. The arms are little affected, and nystagmus and dysarthria may be absent. The typical course is gradual evolution over several weeks or months, after which the disorder remains static for many years. More rarely, slow progression occurs over a number of years. The resemblance to cerebellar degeneration seen with bronchial carcinoma can sometimes be close, and chest radiography is obviously important in every case. CT or MRI may reveal cerebellar cortical atrophy. Gilman *et al.* (1990) have shown hypometabolism in the superior cerebellar vermis with FDG-PET.

Pathological changes are largely restricted to the anterior and superior aspects of the vermis and cerebellar hemispheres. The cell loss affects the Purkinje cells especially. Victor *et al.* (1989) suggest that the ataxia of Wernicke's encephalopathy, at least in its chronic form, is based on a similar type of lesion. They therefore favour a nutritional cause rather than a direct toxic effect of alcohol. There is little evidence to favour the latter, Estrin (1987) finding that estimates of annual and lifetime consumption were *lower* in alcoholics with cerebellar degeneration than in those without. Karhunen *et al.* (1994) have shown a small inverse correlation between Purkinje cell counts and size of daily intake in moderate drinkers, but the variation was wide suggesting important differences in individual susceptibility. Sullivan *et al.* (2000b) have documented correlations between cerebellar grey and white matter volumes and ataxia in alcoholic and Korsakoff patients.

Amblyopia

In rare cases retrobulbar neuritis may develop in alcoholics, progressing over 1 or 2 weeks but rarely extending to complete blindness. Dimness of central vision, especially for red and green, is the more common result. An associated peripheral neuropathy is usual. The smoking of strong pipe tobacco is often incriminated in addition to the alcoholism, and deficiencies of both thiamine and vitamin B₁₂ appear to be responsible. Acute blindness is more commonly seen as a result of methyl alcohol consumption, and is then attributed to the direct toxic effects of the poison.

Marchiafava–Bignami disease

This rare disorder was formerly thought to be restricted to Italian males but this is now known to be erroneous, likewise the belief that it was especially related to the drinking of wine. It presents with ataxia, dysarthria, epilepsy and severe impairment of consciousness, or in more slowly progressive forms with dementia and spastic paralysis of the limbs. Delmas-Marsalet *et al.* (1967) reviewed the literature and

presented cases with full neuropathological examination. Extensive demyelination affects the corpus callosum and adjacent subcortical white matter, the optic tracts and the cerebellar peduncles. The mortality is high, but patients sometimes survive for several years. Recovery is rare. Characteristic findings have been reported in the corpus callosum on CT or MRI (Kawamura *et al.* 1985). A nutritional origin is suggested by the symmetry and constancy of location of the lesions within the CNS, and the frequent history of dietary deprivation. The fact that virtually all cases have occurred in alcoholics suggests that alcohol may also play a part in causation (Victor *et al.* 1989). The precise factors involved remain uncertain.

Central pontine myelinolysis

This is an acute and often fatal complication of alcoholism, presenting with obtundation, bulbar palsy, quadriplegia and loss of pain sensation in the limbs and trunk. Vomiting, confusion, disordered eye movements and coma are common. Some patients show the 'locked in' syndrome with mutism and paralysis but relatively intact sensation and comprehension (Adams & Victor 1993). The lesion lies in the centre of the basis pontis, varying in extent and sometimes involving other neighbouring structures. It consists essentially of a focus of demyelination, usually demonstrable with MRI.

A nutritional origin has again been strongly suspected (Cole *et al.* 1964). Many cases are seen in association with Wernicke's encephalopathy and polyneuropathy. However, it may also occur with liver disease not due to alcohol, with Wilson's disease, and after liver transplantation/haemodialysis (Compston 1993). Other causes include severe burns, hyperemesis gravidarum and diuretic therapy which have led to hyponatraemia. It has emerged that over-rapid correction of low serum sodium is a common cause in such situations, the pons being unusually vulnerable to rapid changes in electrolyte balance due to its close admixture of white matter bundles and richly vascular grey matter (Leslie *et al.* 1980). This has led to the relabelling of the condition as the 'osmotic demyelination syndrome' (Sterns *et al.* 1986).

Barbiturates

The barbiturates are a large class of related compounds based on barbituric acid with sedative hypnotic properties, once widely prescribed for sleep and anxiety disorders, now in greatly restricted use as anticonvulsants (e.g. phenobarbital) and in anaesthesia (e.g. pentobarbital) (Charney *et al.* 2001). A fascinating review of the history of barbiturate use is provided by López-Muñoz *et al.* (2005), detailing the impact of the widespread availability of compounds with effective anaesthetic, anticonvulsant and anxiolytic properties, followed by the later recognition of their addictive and toxic properties, in particular their role in overdose as exemplified by the death of Marilyn Monroe. Acute and chronic toxicity associated with barbiturates reached a peak in the 1960s but

are now uncommon as a result of more stringent prescribing practices. Barbiturate use is associated with increasing tolerance so that ultimately enormous quantities can be consumed, and barbiturate addiction is still occasionally seen, most often along with addiction to alcohol and other drugs.

Acute barbiturate intoxication

The barbiturates display a very narrow therapeutic window, with early anxiolysis followed by a period of confusion and drowsiness giving way to deepening anaesthesia (Charney *et al.* 2001). The pulse and respiration are slowed, the blood pressure lowered, and the body temperature often reduced. The tendon reflexes are diminished, or absent in deep coma. The plantar responses may be upgoing. Nystagmus is a prominent feature in the earlier stages together with tremors of the tongue and lips. Death may result from respiratory failure or peripheral circulatory collapse.

During recovery signs of cerebellar disturbance are marked, with nystagmus, ataxia, asynergia, dysarthria and hypotonia. A muddled euphoria is often seen while consciousness is returning, and a period of hypomania may persist after all neurological features have cleared.

Estimation of the blood barbiturate level serves to confirm the cause of the acute intoxication or coma. EEG may also be useful in showing generalised fast beta activity during the first 24 hours after overdose, unlike most other severe intoxications which produce slowing of rhythms in parallel with reduction of the level of consciousness.

Treatment of an acute overdose of barbiturates requires immediate admission to hospital, with facilities at hand for mechanical respiration and dialysis if required. Induced vomiting, gastric lavage or activated charcoal treatment must be carried out urgently, and measures may be needed to control peripheral circulatory failure. Deepening or prolonged coma may necessitate artificial respiration and the use of haemodialysis.

Chronic barbiturate intoxication

Chronic barbiturate intoxication produces drowsiness, fluctuating confusion, dysarthria and ataxia that may closely resemble drunkenness due to alcohol. Withdrawal effects are also similar, with epileptic fits and delirium. It is still important to consider barbiturate abuse in patients who present with intermittent confusion of obscure origin, or who develop fits or delirium of uncertain aetiology on admission to hospital.

Little has been discovered about possible long-term effects of barbiturate abuse on the CNS. The question has rarely been addressed directly, no doubt because of difficulties in the systematic follow-up of subjects. Moreover, polydrug abuse has been a common pattern in barbiturate addicts, with a large number of sedative, narcotic and stimulant drugs often featuring in the histories of patients.

EEG during barbiturate coma shows diminished amplitude and burst suppression, providing a reliable guide to central effects (Winer *et al.* 1991). After withdrawal dramatic changes occur, with high-voltage paroxysmal discharges or bursts of high-amplitude waves at 4–6 Hz during the first 12–48 hours, with seizures similar to the grand mal fits of idiopathic epilepsy (Essig 1967).

γ -Hydroxybutyrate

γ -Hydroxybutyrate (GHB), also known as liquid ecstasy, is a recently recognised drug of abuse related to the sedative hypnotics and used for its anxiolytic and euphoriant properties (Gonzalez & Nutt 2005). Initially synthesised in the 1960s, the recent increase in the recreational use of GHB, and its association with 'drug rape', has focused attention on the compound and its effects. In a randomised controlled study comparing the effects of GHB with a barbiturate and a benzodiazepine, GHB showed intermediate properties with initial euphoria and reduced anxiety, with higher doses producing sedation and nausea (Carter *et al.* 2006). There is evidence for distinct GHB receptors in the brain, although it is probable that the main mechanism of action is to promote GABAergic neurotransmission (Crunelli *et al.* 2006). GHB abuse is associated with acute hospital presentation, with sedation and paradoxical agitation being the main features but with few other distinguishing features, rendering diagnosis difficult (Drasbek *et al.* 2006).

Benzodiazepines

Benzodiazepines are in common use as short-term anxiolytics, hypnotics, anticonvulsants and muscle relaxants, as add-on therapy to selective serotonin reuptake inhibitors in the treatment of obsessive-compulsive disorder, and as adjunctive therapy in treating patients with acute mania or agitation (Chouinard 2004). Prevalence rates of benzodiazepine use (depending on the definition of benzodiazepine use and observation period) range from 0.2 to 8.9%, with the ratio of female to male use constant at 2 : 1 and longer-term benzodiazepine users usually older than 45 years (Zandstra *et al.* 2002).

Increased awareness of the risks of tolerance, dependence and cognitive side effects has contributed to the decline in the prescription of benzodiazepines over the last two decades (O'Brien 2005a), as has increased availability of alternative pharmacological and non-pharmacological treatments for anxiety and insomnia (Stewart & Westra 2002). The rapid development of tolerance limits benzodiazepine use to brief periods only, typically 2–4 weeks. Discontinuation following the development of physical dependence can lead to severe withdrawal effects that can mimic the symptoms for which the drugs were initially prescribed, with exacerbation of anxiety and insomnia. Patients prescribed therapeutic

doses over long periods may show an admixture of beneficial and withdrawal effects.

There is a variety of compounds in the benzodiazepine class differing in duration of action, potency and primary metabolism (Chouinard 2004). Of those commonly prescribed, nitrazepam, diazepam and flurazepam have longer half-lives compared with lormetazepam, temazepam and oxazepam. Lorazepam is much more potent compared with, for example, diazepam and temazepam. The risk of physical dependence is much greater with shorter-acting compounds. All benzodiazepines are metabolised in the liver through glucuronidation or nitrogen reduction, and eliminated by the kidneys. In patients with impaired liver function (e.g. the elderly, patients with cirrhosis), caution should be used in prescribing, especially those benzodiazepines that undergo liver oxidation, as the oxidative process is more susceptible to liver impairment compared with glucuronidation and nitrogen reduction. Benzodiazepines metabolised by oxidation use the cytochrome P450 3A4 liver enzyme system. Therefore caution is also required in prescribing to patients already receiving medicines utilising this route of metabolism, e.g. ketoconazole, erythromycin, clarithromycin, diltiazem, verapamil, ritonavir (this list not exhaustive).

All forms of benzodiazepines act by enhancing the actions of the inhibitory neurotransmitter GABA by binding to a specific recognition site on GABA_A receptors containing $\alpha 1$ –5 subunits. Compounds that bind at this modulatory site and enhance the inhibitory actions of GABA are classified as agonists, those that decrease the actions of GABA are termed inverse agonists, whereas compounds which bind but have no effect on GABA inhibition are termed antagonists. The clinically used benzodiazepines are full agonists. Attempts have been made to develop compounds that are anxiolytic in that they retain the anxiolytic properties of the full-agonist benzodiazepines but have reduced sedation and dependence liabilities (Atack 2003). Early data suggest that $\alpha 1$ GABA_A receptors may mediate sedation, anterograde amnesia and seizure protection, whereas $\alpha 2$ GABA_A receptors may mediate anxiolysis (Mohler *et al.* 2002).

Research suggests that although benzodiazepine prescribing is high among patients with severe mental illness (e.g. schizophrenia and bipolar disorder) and co-occurring substance misuse disorders, abuse potential is high in this group (Brunette *et al.* 2003) and there is little evidence to support that their use is helpful either for relief of target symptoms of anxiety and depression or for attaining remission from substance use disorder.

Among intentional abusers of benzodiazepines, benzodiazepines are usually a secondary drug of abuse, used mainly to augment the 'high' received from another drug or to offset the adverse effects of other drugs. Few cases of addiction, as opposed to 'normal' physical dependence, arise from legitimate use of benzodiazepines (O'Brien 2005a). The psychiatric complications attending the general use of benzo-

diazepines are best considered first in terms of their withdrawal phenomena and secondly their sedative actions.

Withdrawal effects

Dependence on benzodiazepines can occur very quickly and within therapeutic dosage. Withdrawal effects can follow dose reduction or discontinuation. Adverse reactions are commoner with abrupt than gradual withdrawal, after high dosage or prolonged use, and with shorter-acting forms of benzodiazepine, although there is much individual variability. The symptoms of withdrawal are highly variable from patient to patient. The usual time course for the development of symptoms is within 3–10 days of stopping treatment. Withdrawal is more rapid with compounds that have a short half-life. Lorazepam has been associated with particularly early and severe withdrawal effects. Withdrawal of regular night sedation can precipitate nightmares, vivid dreams and 'rebound insomnia', accompanied by increased REM sleep for several weeks. Discontinuation of daytime treatment can lead to agitation, dysphoria and perceptual changes. Somatic symptoms of anxiety tend to be accompanied by restlessness, emotional lability, impaired concentration and depersonalisation. Insomnia is often severe. Panic attacks and paranoid feelings occur. Weakness, dizziness, tremor, muscle twitching, palpitations, headaches and sweating are common, likewise gastrointestinal symptoms including nausea, anorexia, abdominal discomfort and diarrhoea. Perceptual disturbances have been described in many modalities and include sensations of movement or tilting in the visual field leading to feelings of unsteadiness ('perceptual ataxia'), also tinnitus and unusual tactile sensations. Blurring of vision, facial burning and hot and cold feelings may be accompanied by muscle pain and aching. Increased sensitivity may be experienced to light, sounds, smells and taste. The more florid manifestations last on average 5–20 days, but anxiety-related symptoms can persist for 6–12 months. Severe and dangerous manifestations can follow abrupt withdrawal from large dosage. Confusion and hallucinations may progress to delirious states closely similar to delirium tremens. A serious complication is grand mal fits, sometimes with status epilepticus.

Management of withdrawal

After careful assessment of the reasons for commencing the medication, and of the possible need for continuing alternative treatment, the dosage of benzodiazepines should be very gradually tapered. When the patient is on a short-acting compound, substitution with diazepam may facilitate withdrawal. Propranolol may help to ameliorate some of the somatic symptoms, and clonidine has been claimed to be useful. Sedative antidepressants may be indicated when depression is severe. Anxiety management techniques have been shown to be valuable, and self-support groups have

come to be widely established. A recent Cochrane review of the management of benzodiazepine monodependence (Denis *et al.* 2006) found support for dose-tapering strategies with little current support for substitution of longer-acting agents or adjunctive medications.

Sedative effects

Despite rapid tolerance to benzodiazepines, sedation can continue to occur especially with escalating dosage, leading to slowed cerebration, increased reaction time and decreased vigilance. This can be hazardous in persons using machinery or when driving. When used for night sedation, 'hangover' effects may be troublesome, particularly in older persons, and especially with long-lasting preparations such as nitrazepam. Severe sedation, from cumulative dosage or excessive intake, can result in a picture of intoxication with slurred speech, ataxia, emotional lability and poor memory and concentration. Impairment of judgement may be compounded by a paradoxical increase in hostility and aggression, ranging from excitement to outbursts of anger and antisocial behaviour (Mancuso 2004). Very large doses lead to coma with respiratory depression, although fatalities from overdosage have proved to be rare.

A good deal of interest attaches to the amnesic effects that may be produced, especially with intravenous administration. This has been utilised prior to surgery or uncomfortable investigatory procedures. Wolkowitz *et al.* (1987) gave incremental doses of diazepam intravenously to volunteers, revealing marked effects on attention and word list recognition. At higher dosage the effects could be so profound that the subject could not remember that a word list had been given. In contrast, access to information acquired prior to the injections was totally spared. Lister (1985) and Hartman (1988) review other studies that have shown impaired recall of new material, apparently due to deficient acquisition into long-term memory. The severity and duration of the memory effects vary according to the particular drug used, the dose and the route of administration, but beyond this the pattern appears to be qualitatively the same: impairment of acquisition without effects on retention or retrieval. In some circumstances the drugs may even facilitate retrieval. How far these effects depend on sedation, reflecting attentional processes rather than memory *per se*, remains uncertain.

It is also unclear whether long-continued use can lead to neuropsychological impairment. Observations suggesting that this is so have usually been on patients taking other medications in addition. Lucki *et al.* (1986) studied patients who had taken benzodiazepines continuously for a mean of 5 years, mostly in normal therapeutic dosage. In comparison with matched controls seeking treatment for anxiety-related disorders, there were few demonstrable effects. The free recall of word lists was unaffected, also performance at digit-symbol substitution and letter cancellation tasks.

Impairment was found only on the critical flicker-fusion threshold. Such results would appear to reflect tolerance to the amnesic and other psychological effects of the drugs with long-term use.

Opiates and opioids

The opiates comprise a series of alkaloids derived from the opium poppy *Papaver somniferum*, including morphine, thebaine and codeine, which have a long history of use for relief of pain and diarrhoea, and of abuse for euphoriant effects. Heroin (diamorphine) is prepared from morphine by acetylation and has a particularly marked euphoriant effect. The opioids refer to all drugs with morphine-like action and include synthetic compounds such as fentanyl (and derivatives), methadone, buprenorphine and oxycodone, as well as the endogenous neurotransmitters enkephalin, endorphin and dynorphin. The major and most valuable property of the opioids is pain relief; indeed the opioids are the most powerful and effective drugs for pain relief known, being particularly effective at reducing pain without effects on other sensations. Unfortunately, such a valuable property is also associated with profound abuse liability, and a major source of abused opioids are those diverted from clinical prescription (Cicero *et al.* 2007).

The central actions of opioid drugs have been clarified by the identification of opiate receptors in the brain. These exist as μ (μ), κ (κ) and δ (δ) subclasses, of which the most important for analgesic and euphoriant effects is the μ receptor found widely throughout the nervous system, particularly in the dorsal root ganglia of the spinal cord, the ventral tegmental area and the ventral striatum. It is now known that endogenous opioids present in the nervous system (enkephalins, endorphins and dynorphin) have important modulating effects on pain perception. There is evidence that repeated administration of exogenous opioid drugs leads to suppression of endogenous opioid activity and also to augmentation of stress systems, which lead to an important role in relapse to opioid dependence (Koob & Kreek 2007).

Acute effects

Opiates are administered by a variety of routes, some such as methadone and codeine being orally bioavailable; however, for maximal euphoriant effects rapid administration is preferred. For example, heroin is administered by intravenous injection, termed 'shooting up', or by inhalation, called 'chasing the dragon'. Administration is followed by a euphoriant 'rush' and a subsequent 'high' comprising a state of mental detachment and feelings of extreme well-being. They also have sedative effects ('nodding' or 'gouching'), leading to difficulty with concentration, drowsiness and sleep. After large doses depression of the respiratory centres can cause

respiratory arrest and death. The characteristic sign of pin-point pupils with respiratory failure is virtually pathognomonic of opioid overdose. Established treatment for opioid overdose is intravenous administration of the potent opioid antagonist naloxone, which rapidly reverses opioid coma 'on the point of the needle'; however, care needs to be taken that opioid effects do not return given the short (20-minute) half-life of naloxone (Clarke *et al.* 2005).

With repeated use tolerance develops rapidly so that dangerously large doses come to be taken. In particular a withdrawal syndrome develops, with marked motivational and physical signs of dependence that may disrupt the addict's life by constant drug-seeking behaviour. Physical dependence becomes apparent when administration is disrupted or curtailed. The early opiate abstinence syndrome consists of craving, anxiety, sweating, restless sleep and running eyes and nose. More severe degrees show as gooseflesh ('cold turkey'), shivering, muscle twitching, dilated pupils and aching in the bones and muscles. Abdominal cramps develop later with vomiting, diarrhoea, increased pulse and blood pressure, severe insomnia and low-grade fever. Consciousness is unimpaired throughout. The physical withdrawal syndrome tends to reach a peak during the third and fourth days, usually subsiding within a week. Although extremely unpleasant, it is rarely life-threatening. However, the motivational aspects of the withdrawal syndrome persist, leading to intense craving and increased risk of relapse under conditions of drug-primed, cue-primed or stressful circumstances (Bossert *et al.* 2005). Opioid replacement therapy with long-acting orally bioavailable opioids such as methadone or buprenorphine is directed towards preventing development of the withdrawal state, with relapse to more harmful use of opioids (see Mattick *et al.* 2008 for a Cochrane review of current practice). Given that opioid replacement therapy needs to be given on a continuous and costly basis, non-opioid pharmacotherapies are under assessment, such as the opioid antagonist naltrexone which shows some evidence for prevention of craving and relapse (O'Brien 2005b).

One very important exception to this picture of relatively mild physical withdrawal effects is seen in the neonatal abstinence syndrome, which is marked by neonatal irritability, seizures, growth retardation, failure to thrive and an increase in sudden infant death syndrome. This important source of mortality and morbidity necessitates vigilant opioid replacement treatment in expectant opioid-dependent women (Minozzi *et al.* 2008).

Psychiatric disorder

The use of opiates *per se* appears to be relatively free from adverse effects on the CNS. The major identified problems associated with opioid abuse stem from the complications of intravenous administration, including injection of impurities and transmission of infections such as hepatitis B and C

and HIV. Overdose, deep vein thrombosis and hypoxic brain damage are recognised causes of comorbidity. Neuroimaging studies have identified abnormalities associated with infection, infarction and anoxia in heroin users presenting for treatment, with a relatively rare leucoencephalopathy associated with 'chasing the dragon' (Borne *et al.* 2005). Neuropsychological studies of opioid use, to quote a recent review, 'remains limited' (Gruber *et al.* 2007). They summarise findings suggesting that the use of opiates is associated with multiple deficits in attention, concentration, recall, visuospatial skills and psychomotor speed, with particularly marked effects on executive functions and behavioural inhibition, but these may be premorbid features associated with both inception of heroin use and persistence with heroin use. However, considerable difficulties are encountered in discerning the possible contributions of individual substances when polydrug abuse is so common a pattern. Thus it is hard to make definitive statements on the issue, in contrast to the obvious cerebral toxicity of several other abused substances. This may in itself be a significant observation.

Cannabis and the cannabinoids

Cannabis refers to products of the plant *Cannabis sativa* (and *Cannabis indica*), widespread in tropical and temperate areas. In the form of marijuana and hashish they have a long history of medicinal and ritual use predicated on their psychoactive properties (Clarke & Watson 2002). Cannabis also has practical use in the form of hemp – strong fibres derived from cannabis used in the production of rope and other fabrics – which may have contributed to the widespread availability of this plant and served as a base for later adoption to psychoactive use. The importance of cannabis and the cannabinoids stems from their current status as the most widely abused illicit drugs within Western societies, their potential medicinal use and their relationship to psychiatric disorder, particularly psychosis and schizophrenia. The cannabinoids comprise the 60-plus cannabis-derived compounds, most importantly Δ^9 -tetrahydrocannabinol (Δ^9 -THC) derived from *Cannabis sativa* and current synthetic variants, which contribute to psychoactive use. Accepted medical uses of cannabinoids (currently Marinol or Dronabinol, an oral preparation of Δ^9 -THC) include treatment for refractory nausea and vomiting associated with chemotherapy and for weight loss associated with anorexia in AIDS and HIV infection.

Cannabinoids, particularly Δ^9 -THC, have been shown to exhibit reinforcing effects in animal models, including self-administration and conditioned place preference, and to show tolerance and withdrawal following chronic use. These findings should serve to curtail the frequently encountered question about whether such phenomena are true of human use, but rather focus attention on the nature and degree with which they are present. Using such models, it has been possible to identify important contributions of the endogenous

dopamine and opioid systems to the behavioural effects of cannabinoids, and to detect endocannabinoids such as anandamide that have neuromodulatory function within reinforcement systems in the brain. Two cannabinoid receptors, CB₁ (central) and CB₂ (peripheral), have been identified, with the CB₁ receptor clearly implicated in the behavioural effects of cannabinoids. In a series of studies of CB₁ receptor knockout models, attenuation of opioid effects was also demonstrated (Martin *et al.* 2000), emphasising that the effects of opioids are contingent on intact cannabinoid signalling and that cross-talk between systems is often important for the net drug effects to a single agent.

Contemporary views on cannabis use have tended to become an emotive and highly politicised topic, specifically with respect to how control is best achieved through regulation and policing and the status of cannabis as a ‘gateway’ drug to more harmful drug use. While there is still uncertainty about the prevalence of seriously adverse psychological reactions to the drug, and case reporting has perhaps highlighted the rare and exceptional, the current prevalence and early inception of psychoactive use is such that cannabis use must nowadays be increasingly considered in psychiatric differential diagnosis. Both acute and chronic forms of adverse reaction have been described, the main difficulty being how far these reflect special vulnerability in the patient rather than the direct neuroadaptive properties of cannabis on the nervous system. The relationship between cannabis / cannabinoids and psychiatric disorder is considered here with respect to general behavioural properties of psychoactive use, neuropsychological effects and long-term abstinence effects, as well as their putative and controversial relevance to schizophrenia.

Acute effects of cannabis

Cannabis is most often smoked, with effects noted within 10–15 minutes, but can also be ingested with delayed onset of effects and prolonged action. The active ingredient, Δ^9 -THC, has high lipophilicity, which contributes to rapid onset of psychoactive effects. The effects of ingesting or smoking marijuana are distinctive and were described in early reports by Bromberg (1934) and Allentuck and Bowman (1942). Since these early reports, multiple studies have been conducted under both naturalistic and controlled conditions examining acute and non-acute (residual) effects on subjective experience and neuropsychological function (reviewed by Gonzalez *et al.* 2002; Gonzalez 2007).

The most common reported effect of cannabis use is one of ‘relaxation’, although there is considerable variation in effects between both individuals and occasions (Green *et al.* 2003). Other responses include happiness, laughter and increased sensory perceptions. Negative effects are uncommon and include dizziness, drowsiness, paranoia, anxiety and depression, and occasionally depersonalisation

(Gonzalez 2007). Cognitive functions are affected in many subtle ways. The stream of talk tends to be circumstantial and fragmented. There may be difficulty in linking parts to the whole, or sudden interruptions in the stream of thought resembling the blocking of schizophrenia. Time sense is characteristically distorted, often with remarkable subjective lengthening of time spans. Sometimes there is unawareness of the passage of time, or a curious disturbance in which the present does not seem to arise out of the past. Attention, concentration and comprehension are only slightly impaired in the milder stages of intoxication, although retrieval-based memory deficits have been consistently observed (Gonzalez 2007). Effects of Δ^9 -THC have been noted with respect to other cognitive functions, including measures of decision-making and inhibition, but these may relate to risk variables rather than the consequences of cannabis use *per se*. Intriguingly, in one laboratory-based controlled study, haloperidol treatment did little to affect the subjective experience of Δ^9 -THC and *worsened* neuropsychological performance, indicating that the effects of Δ^9 -THC are not substantially mediated via dopaminergic neurotransmission (D’Souza *et al.* 2008a).

Tolerance to cannabis is now well recognised (D’Souza *et al.* 2008b), as is the existence of a cannabis withdrawal syndrome marked by irritability, aggression, decreased appetite and sleep disturbance (Budney *et al.* 2004). Studies of the non-acute (residual) effects of cannabis have been reviewed by Gonzalez *et al.* (2002), who established basic criteria for inclusion of studies into a meta-analysis. Relatively few studies met such criteria, but supported mild residual effects of cannabis on learning and memory performance, which are alleviated by abstinence, with some evidence of diminished decision-making. In the absence of longitudinal studies, these may relate to pre-existing deficits.

Cannabis and psychiatric disorder

The claim that excessive use of cannabis over long periods of time can result in a chronic psychotic illness akin to schizophrenia, or indeed increase the risk of developing schizophrenia *per se*, is currently a subject of intense controversy. While there is an emerging consensus that cannabis use is a risk factor for developing schizophrenia (Arseneault *et al.* 2004; Moore *et al.* 2007; Murray *et al.* 2007), strong evidence about the magnitude of risk from cannabis use has been hard to obtain and the hypothesis needs to be viewed with caution. When chronic psychoses have developed there may have been important predisposing factors or even pre-existing illness; and where social decompensation is concerned much may be due to social or subcultural influences. A historical study by Halikas *et al.* (1972), in which 100 regular cannabis users were interviewed along with 50 non-user friends of the group, showed clearly how it could be erroneous to attribute causal significance to the drug. A high prevalence of psycho-

pathology was found in both samples, approximately half of each fulfilling criteria for some psychiatric diagnosis. Moreover, almost every diagnosed psychiatric illness among the users had begun before the first exposure to cannabis.

Early examples of *prolonged depersonalisation* lasting for months after cannabis use have been cited, sometimes after relatively brief exposures (Keshavan & Lishman 1986). The patients often considered their chronic symptoms to be identical with those experienced during acute intoxication, adding to the suspicion that neurobiological factors could be responsible. Nevertheless, more recent controlled studies found little evidence for a distinct drug-induced depersonalisation syndrome (Medford *et al.* 2003).

With regard to the *chronic psychoses*, it is generally viewed that cannabis use exacerbates symptomatology, likelihood of relapse and the severity of social impairment, although a recent Cochrane review still regarded the evidence as equivocal (Rathbone *et al.* 2008).

Evidence of *cognitive impairment*, especially some time after cannabis exposure, has been hard to demonstrate after controlling for premorbid cognitive function. Iversen (2005) reviewed the evidence for a link with the somewhat surprising conclusion that 'cannabis could be rated to be a relatively safe drug'. Investigation of structural or functional brain changes associated with cannabis use has been the subject of recent review by Quickfall and Crockford (2006) who analysed in excess of 100 studies on this topic. In general, no strong structural abnormalities were associated with cannabis use. Functional impairments were associated with increases during acute use and decreases during abstinent periods, analogous in many respects to use of psychostimulant drugs in general, without particular specificity for cannabis use *per se*.

Psychostimulants

Cocaine, amphetamines and methamphetamine

The psychostimulants cocaine, amphetamine and methamphetamine comprise a group of drugs with analogous effects to adrenaline (epinephrine) and are often referred to as 'sympathomimetic amines'. They stimulate the CNS and also activate the sympathetic nervous system, producing increased activity, excitement and euphoria. They have a long history of use to alleviate fatigue in the form of tonics (perhaps the most famous example being CocaCola) and a correspondingly long history of abuse and behavioural toxicity. Currently, the most prevalent psychostimulant in the UK is cocaine, although worldwide methamphetamine abuse in the form 'crystal meth' is arguably the greater problem (Buxton & Dove 2008). Prior to the escalation in the use of cocaine, amphetamines were the most abused psychostimulant, and abuse is occasionally seen even now. Sloboda (2002) has highlighted the difficulties in assessing the preva-

lence of psychostimulant (and other illicit drug) abuse, which occurs largely in illicit markets and hence limits the planning of interventions targeted either on supply of the drug or on dealing with the consequences of abuse.

The use of cocaine has a long history. The alkaloid is obtained from the leaves of the coca bush (*Erythroxylum coca*) which is grown extensively in Colombia, Bolivia and Peru. Coca paste, a crude derivative of the leaves, may be chewed or smoked, but most of the crop is converted into cocaine hydrochloride and sold as a powder, often mixed with various adjuvants. This can be inhaled into the nose (sniffing or snorting) or injected intravenously. Freebase forms are derived from the hydrochloride as preparations suitable for smoking, a simple process yielding the form known as 'crack'. Tiny pellets of crack, representing pure crystalline cocaine, are sold remarkably cheaply and rapidly lead to the most severe form of addiction. Animal experiments have shown that cocaine is a powerful primary reinforcer, largely mediated through the dopaminergic system (Thomas *et al.* 2008), leading the animal to work for drug reward to the exclusion of food and often until death.

Medical use of the amphetamines is now largely restricted to the treatment of narcolepsy (dexamfetamine sulphate, racemic amphetamine sulphate, methylphenidate; see Chapter 13) and of children with attention deficit hyperactivity disorder. Ephedrine, the earliest member of the group, is mainly employed as a nasal decongestant, and its derivatives are ingredients of over-the-counter cold cure remedies: pseudoephedrine (Sudafed), phenylpropanolamine (Triogesic) and phenylephrine. Other related compounds have been used for the treatment of obesity though this is now discouraged: phenmetrazine (Preludin), diethylpropion (Apisate), phentermine (Duromine). Many patients have become dependent as a result of careless prescribing, and all drugs in the group may be abused for their stimulant and euphoriant effects. The use of methylamphetamine (Methedrine) by intravenous injection presented particular problems during the 1960s. Stricter prescribing controls are nowadays offset by illegal manufacture.

Physical and psychological effects

In whatever form they are taken the psychostimulants exert powerful stimulant and euphoriant effects, leading to increased energy and wakefulness for a time and feelings of great well-being. Intravenous use produces an intense 'rush' or 'high' almost instantaneously, gradually receding over 20–30 minutes. The smoking of 'crack' cocaine has a similarly rapid effect, peaking after 5 minutes or so then abating quickly leaving the addict craving another dose. Nasal inhalation leads to a more gradual onset of euphoria, since vasoconstriction occurs within the nasal mucosa. The effects then typically wear off over an hour or so. While under the influence of the drug the subject shows enhanced alertness and mental acuity and feels increased confidence in social

interchange. Cocaine is often regarded as an aphrodisiac because of the elation and disinhibition experienced, but higher doses lead to impotence and decreased sexual desire.

The stimulant effect on the sympathetic nervous system leads to tachycardia, raised blood pressure, increased temperature and dilated pupils. Important effects are also exerted on the dopaminergic system, especially in mesolimbic and mesocortical areas (Thomas *et al.* 2008). Large doses can result in a dangerous degree of hypertension, cardiac dysrhythmias or grand mal convulsions. Adulterants by way of procaine or lidocaine increase the risk of cardiovascular complications or status epilepticus. Other toxic effects include muscle twitching, nausea and vomiting, irregular respiration and hyperpyrexia.

Sudden fatalities can occur from cardiovascular complications such as myocardial infarction, ventricular fibrillation or cerebral haemorrhage. Other deaths result from CNS depression, with circulatory and respiratory failure, loss of reflexes and delirium. Unexplained deaths are thought to be due to toxic effects on the myocardium. Persons with a congenital deficiency of pseudocholinesterase are at special hazard from even small doses since this enzyme metabolises cocaine.

Severe malnutrition is common in regular abusers who often present with multiple vitamin deficiencies. The powerful local anaesthetic effect of cocaine serves to obscure pain, so that dental neglect can reach extreme degree. Many addicts therefore present in a severely deteriorated state.

It was formerly thought that tolerance did not occur, based on experience of occasional recreational users of the drug. However, it is now clear that users of freebase forms can come to tolerate immense and frequently repeated doses, with adaptation to the convulsant and cardiovascular effects. It is less clear whether tolerance develops to the euphoriant properties though this is likely.

Behavioural toxicity develops rapidly and soon becomes a major problem. Even the casual weekend user is prone to find that little is enjoyable without the drug, and progresses to more frequent and dangerous forms of administration. As the dosage increases dysphoric effects emerge in the wake of elation, with depression, irritability, anxiety and profound insomnia. Severe craving and intense drug-seeking behaviour can then become entrenched. Withdrawal results in a state of depression, apathy and increased appetite, with lethargy and disinterest often persisting for many weeks. Suicidal feelings are not uncommon. Physical aspects of withdrawal include disturbed sleep patterns, tremors and muscle pain, but the major physiological disruptions seen with opiate and sedative withdrawal do not occur.

Psychostimulants and psychiatric disorder

The psychiatric effects of psychostimulants can be considered in four successive stages: acute intoxication, withdrawal depression, addiction and, most dramatically,

hallucinosis and psychosis. The euphoria of acute intoxication, already described above, shows symptoms analogous to mania, with heightened pleasure, hyperactivity and increased speed of intellectual functioning. Disinhibition and impulsive behaviour are common, including a proneness to violence. A second stage, following withdrawal of the psychostimulant, is marked by dysphoria and can resemble major depression, with anxiety, misery, apathy and irritability occurring when psychostimulant levels are falling or in more prolonged abstinence when the addict is craving another dose. Restlessness and hostility can be prominent and alcohol or other drugs may be used to combat such phases. Distinguishing major depression from cocaine (or other psychostimulant) withdrawal can be a difficult diagnostic problem, most readily resolved by brief psychiatric admission. In a recent review of the syndrome, Rubin *et al.* (2007) demonstrated that measures of depressed mood in cocaine withdrawal resolved with brief abstinence, whether or not overt 'major depression' had been evident. Cocaine and psychostimulant addiction have been associated with subtle neuropsychological impairments, particularly affecting executive and attentional processing, with diminished cognitive control leading to impulsivity (Ersche & Sahakian 2007; Garavan & Hester 2007), although these features may be associated with either inception or persistence of psychostimulant use rather than the consequence of use *per se*.

Psychostimulant use is associated with the development of substance-induced psychotic disorder, which is a surprisingly heterogeneous category. The manifestations are probably closely related to elevated dopamine activity in the brain. In a recent review of this disorder, Mathias *et al.* (2008) noted that many of the publications related to single cases with 'a striking paucity of information on the outcome, treatment, and best practice for substance-associated psychotic episodes'.

Amphetamine or cocaine hallucinosis usually begins with visual and auditory misperceptions. Harmless objects and noises appear to be threatening and the person is hypervigilant and increasingly concerned. Halo effects may appear around lights, or sensations of movement at the periphery of the visual field. Hallucinations then emerge in several modalities: lights sparkling at the periphery of vision ('snow lights'), voices calling the user's name, and the classic tactile hallucinations of insects felt crawling under the skin. At this stage partial insight is retained into the unreal nature of the hallucinations and delusions.

Amphetamine or cocaine psychosis represents further progression to extreme paranoia. It is usually preceded by a transitional period of increasing suspiciousness, ideas of reference, dysphoria and compulsive behaviour (Weiss *et al.* 1994). The patient is restless and talkative, and everyday events are

misinterpreted in delusional fashion: he believes others are plotting against him or about to attack him, or that he is being followed by the police or drug dealers. He may act on such beliefs with unusual aggressiveness, damaging property or becoming homicidal or suicidal. Insight is lost into the unreal nature of the hallucinatory experiences; he may pick and scratch at his skin in the search for insects or even claim to see them. A further characteristic feature is repetitive stereotyped behaviour, such as dismantling and reassembling a watch or radio over and over again, or compulsively arranging and rearranging a set of objects (Ghodse 1995). Consciousness is fully preserved throughout and there is no disorientation.

Neurological complications

Glauser and Queen (2007) review the multiple non-cardiac complications associated with cocaine and psychostimulant abuse and their relationship to method of administration. Headache, convulsions and cerebrovascular accidents following acute psychostimulant administration are well recognised, with rarer complications such as spinal cord thrombosis documented. All such events could occur in new or occasional users as well as in chronic addicts.

Cerebral vasculitis represents another hazard. This was first suspected in intravenous drug users from angiographic findings, with irregular segmental constrictions in intermediate-sized arteries and complete obstruction in smaller vessels (Rojas *et al.* 2005). The picture is complicated by poly-drug abuse and impurities in the injected material, or by sepsis, which could have been chiefly responsible.

Treatment

Treatment of acute toxic reactions may require barbiturates or diazepam to control severe agitation, overstimulation or seizures (Estroff & Gold 1986). Propranolol helps with tachycardia and hypertension, and further drugs may be needed to deal with cardiac dysrhythmias. Impending circulatory and respiratory failure will warrant urgent supportive measures. Respiratory depression may indicate that opiates have been taken as well, requiring the administration of naloxone. Chlorpromazine or haloperidol may be needed for the control of psychotic reactions.

Approaches to treatment of psychostimulant addiction are largely psychosocial (Knapp *et al.* 2007), as psychopharmacological trials with anticonvulsants (Minozzi *et al.* 2008), antipsychotics (Amato *et al.* 2007), dopamine agonists (Soares *et al.* 2003) and antidepressants (Lima *et al.* 2003) have been shown on meta-analysis and review to offer no great promise.

Ecstasy and the substituted amphetamines

The substituted amphetamines are a large series of so-called designer drugs arising from combinatorial chemical substi-

tutions based on the core amphetamine (phenylethylamine) molecule. Ecstasy (3,4-methylene-dioxymethamphetamine, MDMA) is the most widely known of these compounds, on which this section focuses. However, the substituted amphetamines also include 'Eve' (3,4-methylene-dioxyethamphetamine), 'STP' (2,5-dimethoxy-4-methylamphetamine) and 'DOB' (2,5-dimethoxy-4-bromoamphetamine), which are among the most well known of an astonishing number of unfamiliar or less fashionable varieties. The famous (or infamous) book *PiHKAL: Phenethylamines I Have Known And Loved* by the biochemist Alexander Shulgin details the synthesis and subjective effects of over 100 of these compounds: the book is legally available, the compounds are not, despite the fact that it serves as the source of methods for the clandestine synthesis of this group of compounds.

Ecstasy (MDMA) became well known in the UK in the 1980s in the context of 'raves' (parties organised for energetic dancing) as a euphoriant and to promote feelings of closeness to others. Along with mild stimulation it has some hallucinogenic potential. From time to time it attracts widespread publicity from the sudden tragic deaths that occur, occasionally on first contact with the drug. Tolerance occurs gradually with repeated use, some habitués taking as many as 10–20 tablets during the course of a weekend (Winstock 1991). However, it does not appear to cause physical dependence, although a large research effort has been directed towards the identification of long-term neurotoxic effects of use. While less newsworthy currently, epidemiological surveys in Europe and the USA (National Epidemiologic Survey on Alcohol and Related Conditions) indicate stable and substantial prevalence of use (Keyes *et al.* 2008).

Acute and subacute effects

The acute subjective effects of MDMA use have been well studied from the 1980s onwards. In a comprehensive review of 24 such studies, Baylen and Rosenberg (2006) identified the major categories of subjective effects as 'emotional (e.g. anxiety, depression, closeness, fear, euphoria, calmness) or somatic (e.g. nausea/vomiting, bruxism, muscle aches/headache, sweating, numbness, body temperature changes, fatigue, dizziness, dry mouth, increased energy)'. Interestingly, cognitive effects such as confused thought, perceptual effects such as sensory disturbance and sleep effects such as insomnia were not reported in more than five of the 24 studies, indicating that while they do occur, this is not the experience of the majority of users. In their review of placebo-controlled healthy volunteer studies, Dumont and Verkes (2006) noted marked psychostimulant effects (elevation of heart rate and systolic and diastolic blood pressure) at doses of 1 mg/kg and above occurring together with the characteristic subjective effects. MDMA is typically taken a stereotyped fashion in doses of about 150 mg, with onset of action within an hour and typically lasting 8 hours, with notable subacute effects lasting days. In a study focusing on these

subacute effects, Verheyden *et al.* (2003) questioned 466 regular users of MDMA and identified the experience of low mood and impaired concentration in about 80%.

MDMA use has been strongly linked to episodic acute toxicity and death, occurring through a variety of mechanisms (Schifano 2004). The more prevalent complication is hyperpyrexia, arising from the psychomotor stimulant effects, compounded by vigorous dancing and environmentally induced overheating, leading to states of collapse due to dehydration and metabolic acidosis. Conversely, attempts to counter such dehydration can lead to water intoxication and inadvertent hyponatraemia. Convulsions, cerebral haemorrhage, rhabdomyolysis, disseminated intravascular coagulation and acute renal failure have all been reported. Such acute adverse reactions can require urgent medical intervention, with active cooling measures, control of seizures, rehydration and other supportive measures. Long-lasting residual sequelae of acute toxicity is often underestimated: Kopelman *et al.* (2001) reported medial temporal, thalamic and retrosplenial hypometabolism on FDG-PET, associated with profound and sustained amnesia, in such a case.

Long-term consequences

Relatively early after MDMA use became prevalent in the 1980s, it was shown to be a selective serotonergic neurotoxin in animal models, producing a rapid and persistent decrease in brain 5-hydroxytryptamine (5HT) and 5-hydroxyindoleacetic acid in experimental animals (McKenna & Peroutka 1990). Of particular note, structural damage was also shown in non-human primates, affecting serotonergic fibres in the cortex and cell bodies in the dorsal raphe nucleus (Ricaurte *et al.* 1988). The mechanisms by which MDMA produces selective serotonergic toxicity comprise a combination of oxidative stress, excitotoxicity and mitochondrial dysfunction (Quinton & Yamamoto 2006), leading particularly to depletion of monoamine neurotransmitters including serotonin and dopamine. Such consistent findings have prompted substantial research into potential long-term neuropsychiatric sequelae in human users of ecstasy, leading to currently in excess of several hundred studies. A range of psychiatric and neuropsychological problems have been identified in current regular ecstasy users and ex-users, with low mood, anxiety and subtle attention and memory deficits being the most consistent findings (reviewed by Karlsen *et al.* 2008). However, the overall conclusion of these studies is that it is not possible to dissociate specific effects due to MDMA over and above those associated with premorbid risk factors and polysubstance misuse, a point highlighted by Gouzoulis-Mayfrank and Daumann (2006). A review of structural and functional MRI studies has not identified any consistent findings, although PET ligand studies have identified potential deficits in serotonin transporter densities in line with the animal literature (Cowan 2007). While the unclear picture emerging from neuropsychological and

neuroimaging studies has led to questions about the animal data, focusing on interspecies differences and dose-scaling assumptions (Easton & Marsden 2006), there is a pressing need for appropriately designed longitudinal studies of sufficient power to detect potential neurotoxic effects of MDMA in humans.

Hallucinogens

Hallucinogens, also known as psychedelics (from the Greek meaning 'to make visible the psyche'), are psychoactive substances that may dramatically alter visual, auditory, gustatory and tactile perceptions, and associated cognitions and consciousness. They are generally not associated with dependence or addiction, or physiological toxicity, but this must be viewed with caution. The explosion in use of the hallucinogens, particularly lysergic acid diethylamide (LSD), from the 1950s onwards has provided the basis for our current knowledge of their potential toxic effects, although it should be noted that the use of naturally occurring hallucinogens has been an important part of human ritual and search for ecstatic experience from the earliest times. Interestingly, research into the properties of these compounds first focused attention on the importance of the serotonin system in cerebral disorder, particularly in the generation of 'model psychosis' (Nichols 2004). This section focuses on LSD, while a multiplicity of other drugs with similar hallucinogenic properties to LSD are not discussed in detail. Of these latter compounds, one group are derived from plants and enjoy a vogue in certain parts of the world. Mescaline comes from a cactus grown in Mexico and nearby parts of the USA, and psilocybin and psilocin from 'magic mushrooms' found in a variety of regions. Mace, nutmeg and the morning glory plant contain other hallucinogenic substances. Another group comprising a range of synthetic compounds with hallucinogenic and amphetamine-like activity have also been widely abused: dimethyltryptamine, dimethoxyamphetamine and dimethoxymethylamphetamine, all largely based on a phenethylamine structure.

Phencyclidine (PCP, 'angel dust') is related to pethidine and has been widely abused in North America. Its use is particularly hazardous on account of a tendency to precipitate convulsions and coma, and its unpredictable psychological effects including outbursts of violent bizarre behaviour and prolonged psychoses.

Lysergic acid diethylamide

LSD is an indole derivative of ergot and can be manufactured synthetically. It is the most powerful hallucinogen known, doses as small as 25 µg usually having a demonstrable effect on humans. The mode of action on the brain is thought to be inhibition of the serotonergic system, via stimulation of pre-synaptic 5HT₂ receptors and consequent feedback effects

on serotonergic neurones (Kosten 1990). Soon after its discovery it enjoyed a vogue in experimental psychiatry for the study of 'model psychoses' that could be induced in normal subjects. Thereafter it was employed as an adjunct in psychotherapy, for abreaction and to assist in the recall of long-forgotten experiences. As a result the acute effects of its administration were closely studied and formed the basis of a good deal of theoretical speculation. Nowadays administration under medical supervision is almost unknown, but the drug continues to be widely taken on an illicit basis. The benefits claimed by users include augmented aesthetic sensitivity, enhanced creativity, the occurrence of transcendental experiences, the acquisition of new insights, and aphrodisiac effects. None of these has been properly substantiated. It is widely abused by unstable individuals in search of dramatic experiences, and often by those who abuse other drugs as well. As a drug of abuse LSD carries the special hazard that it can easily be administered surreptitiously without the subject's knowledge, resulting in profoundly disturbing effects that may sometimes lead to psychiatric referral. When taken at intervals of more than 1 week the reaction is just as intense with the same repeated dose; there is no evidence that LSD is a drug of addiction in the sense of creating physical dependence, and there are no withdrawal effects on discontinuation. The danger lies rather in psychological dependence on the effects that are produced.

Acute effects of ingestion

The acute effects are well described by Isbell *et al.* (1956) and Freedman (1968). There is some variation in individual susceptibility, but striking psychological changes usually follow doses in the range 20–120 µg. The predominant effects with small doses are autonomic changes and alterations of mood, while larger doses produce perceptual distortions, vivid hallucinations and striking subjective changes in body image. These remarkably intense phenomena are usually not accompanied by clouding of consciousness or demonstrable impairment of intellectual processes; indeed a heightened state of awareness is maintained, and thought processes characteristically remain clear. The subject becomes preoccupied with the phenomena he is witnessing and experiencing, but usually retains insight into the fact that they are due to the drug. In these respects the 'toxic' state resulting from LSD and related hallucinogens is very different from the acute organic reactions induced by most other agents.

The autonomic effects are the first to appear. They include dilatation of the pupils, piloerection and some rise in body temperature. The tendon reflexes are often increased, and muscular tremors and twitching develop in severe reactions. Weakness, somnolence and giddiness may be marked. The earliest mood changes are of euphoria or anxiety. Euphoria is usually the predominant change and may extend to feelings of ecstasy, but this can be followed later by sudden swings to

depression, panic or a profound sense of desolation. Some subjects become active and excited, while others are quiet, passive and withdrawn. Some are overwhelmed with a sense of mystical experience. Others become paranoid and hostile to their surroundings. Much probably depends on the pre-morbid personality of the subject, his expectations and the setting in which the drug is taken.

Perceptual distortions, illusions and hallucinations are mainly in the visual sphere but can affect all modalities. Vision may be blurred or astonishingly enhanced and vivid. The perception of depth and distance is changed, size and shape distorted, and colour greatly intensified. Hearing may be dulled or hyperacute, clothing may feel like sandpaper, or the body may feel extremely light or heavy. Synaesthesia often occurs and is fascinating to the subject: sensory data are transformed from one modality to another so that sounds or tactile stimuli appear as bursts of light or scintillating moving spectra. Hallucinations are again mainly visual and occur in both unformed and formed varieties: kaleidoscopic patterns of light in intense and changeable colour, or complex visions of animals and people. Tactile paraesthesiae, metallic tastes and strange smells are not uncommon, but auditory hallucinations are rare.

Distortions of body image can figure prominently and take bizarre forms. Customary boundaries become fluid, so that the patient feels he is one with the chair on which he is sitting or merged with the body of another. His own hands and feet may appear to be transformed into claws or the extremities of a dead person. Sometimes intense somatic discomfort is experienced, with feelings of being twisted, crushed or stretched. Depersonalisation and feelings of unreality may extend to the impression of being outside one's own body, difficulty in recognising the self in a mirror, or difficulty in deciding whether a thought refers to a real event or is merely a spontaneous thought.

Despite these experiences the subject is able to respond to questions, and conceptual and abstract thinking can usually be shown to be substantially intact. Except in the most severe reactions a large measure of critical self-judgement is preserved. However, as the effects of the drug increase, external reality becomes progressively less intrusive and self-control may be lessened, occasionally with dangerous results as described below. Frank delusions may occasionally be expressed but an organised delusional system rarely develops.

The effects of the drug are usually apparent within 30 minutes of ingestion, rising to a maximum 1–4 hours thereafter. The reaction subsides gradually over the next 8–16 hours and there is usually no residuum on waking next morning. However, after the vivid effects of the drug experience, the real world often appears to be drab and dull, and natural events lack the urgent and compelling quality of what has gone before. Some degree of depression and disillusionment may thus be an understandable aftermath.

Adverse reactions

Among habitual users the great majority of LSD experiences are apparently without adverse effect. Occasionally, however, profoundly disturbing results accompany the acute effects of the drug, and lead to emergency medical referral or trouble with the police. Adverse effects appear to be commoner in unstable subjects. Certainly a large proportion of those coming before psychiatrists have a history of previous psychiatric care (Ungerleider *et al.* 1966). It has been estimated that less than 0.1% of normal subjects experience seriously adverse reactions when LSD is taken under medical supervision; among patients undergoing psychotherapy the incidence rises to 0.2–1.0%, and among psychotic subjects to 1–3% (Louria 1968). The frequency among illicit users is unknown but is probably higher still. Much may also depend on the circumstances in which the drug is taken, on impurities in the preparations used and on injudicious doses.

The pictures that result have been described by Frosch *et al.* (1965), Ungerleider *et al.* (1966), Bewley (1967) and Freedman (1968). They may be divided into acute emotional disturbances, the acting out of impulses, and acute psychotic reactions.

Acute emotional disturbances are the most common, especially an acute panic reaction in which the subject feels overwhelmed by experiences beyond his control. He may feel that he is going insane or react in terror to homicidal impulses. He may present himself at hospital seeking relief, or be brought by friends who fear he will come to harm. There is no impairment of consciousness, although recollection of the details of the LSD experience may be hazy. Rapid recovery occurs as the drug effects wear off, usually within 8–12 hours, though sometimes 1 or 2 days are required to regain normality. Other acute emotional disturbances include depression, paranoia and outbursts of explosive anger. Profound depression very occasionally leads to attempted or successful suicide. Acute paranoia may cause the subject to flee about the streets in terror or lead to episodes of explosive anger.

The acting out of impulses is facilitated as self-control becomes diminished. The subject may become unmanageable, run amok, attempt to disrobe or make overt homosexual advances. Sociopathic individuals are more prone to commit acts of violence and attempted homicide has been reported. Feelings of invulnerability may lead the patient to take unwarranted risks with danger of bodily harm. Patients who have fallen from windows or roofs have sometimes apparently acted on the belief that they would float down unharmed.

Acute psychotic reactions are commonly longer lasting, and the majority of Ungerleider *et al.*'s (1966) patients remained in hospital for more than a month. Most are schizophrenia-like illnesses, with hallucinations, delusions and overactive

behaviour. Less commonly they take the form of acute organic reactions with confusion, disorientation and marked emotional lability. However, the latter may often be the product of multiple drug abuse.

Hatrick and Dewhurst (1970) reported two interesting examples in which psychotic illnesses followed a latent interval, well after the effects of acute intoxication had subsided. The illnesses were nevertheless coloured by phenomena reminiscent of the acute phase of intoxication. Both patients were said to have been previously stable and well adjusted, and the illnesses followed a single exposure to LSD.

Features that may be of diagnostic significance in LSD-induced psychoses are discussed by Dewhurst and Hatrick (1972). A particularly striking aspect may be the wide variety of schizophreniform, affective and neurotic symptoms present in the same patient. Suggestive symptoms include regression to childhood, loss of time sense, grandiose delusions of a pseudophilosophical nature, and a wealth of visual hallucinations and perceptual disturbances. Visual hallucinations are said to be more intense than in other acute organic reactions and may be specific, transient and recurring. Auditory hallucinations tend to have a more startling, personal and realistic quality than in schizophrenia. The emotional response is usually constantly shifting, with apprehension, panic, elation or depression in rapidly changing sequence. When an LSD-induced psychosis presents as hypomania, euphoria may alternate with panic, which is an unusual combination in primary affective illness. Many patients with suicidal ruminations have irrational compulsive urges to self-destruction, arising suddenly and sometimes unbacked by other depressive symptoms.

Rosenthal (1964) drew attention to a further rare type of prolonged reaction, consisting of visual hallucinosis in clear consciousness. Rosenthal considered this to be specifically related to multiple exposures to LSD over a considerable period of time. The condition is often heralded by a change in the experience produced by the drug, typically a change to unpleasant reactions that may have led to its discontinuation. Spontaneous visual hallucinations then commence and continue for many months. The hallucinations are similar in form and content to those experienced under the drug: droplets of colour, shimmering panels and brightly coloured shape distortions. Cats, crabs, insects and corpses may also be seen. Pleasant hallucinations were often under semi-voluntary control, in that the patient could make them more or less intense by efforts of concentration, but the unpleasant phenomena were intrusive and liable to provoke severe anxiety. The patients continued to recognise the unreality of the hallucinations, and there was no evidence of thought disorder or other schizophrenic phenomena. Occasionally, however, a secondary delusional system was elaborated to explain the hallucinations.

The issue of longer-term neuropsychological deficits associated with long-term hallucinogen use has been addressed

in a meta-analysis and review by Halpern and Pope (1999) who conclude that the evidence for any consistent deficits are at present equivocal and are methodologically confounded by polysubstance misuse in this group.

Recurrences of the LSD effect (flashbacks)

Occasionally, there may be a simple prolongation of the LSD state lasting several days, with undulating anxiety and persisting visual aberrations, but Frosch *et al.* (1965) have described more remarkable phenomena in which the LSD experiences recur for many weeks or months after discontinuation of the drug. Sometimes it is merely bewilderment or fear that recur in milder form, but quite commonly sensory phenomena are involved as well. Two of Frosch *et al.*'s patients experienced depersonalisation and perceptual distortions 2 months later. Another had many transient episodes of catatonia and visual hallucinations over the course of a year, similar to those that had been induced by LSD.

Horowitz (1969) suggests that perhaps as many as 5% of users experience mild recurrences from time to time, while others have put the estimate much higher. Sensory recurrences have been reported in all modalities, but the visual system is most often involved. Horowitz described three main varieties. The commonest consists of the repeated intrusion into awareness of some image derived from the LSD experience. This arrives unbidden and is outside voluntary control. It may be accompanied by distortion of time sense or reality sense. It is usually the same image that recurs, often of a frightening nature, and considerable psychiatric disturbance can occasionally be provoked. The second variety consists of the spontaneous return of perceptual distortions: halo effects, blurring, shimmering, reduplication, distortion of planes, changes of colour, micropsia or macropsia. In the third variety there may be increased sensitivity to spontaneous imagery for some time after taking LSD. Such imagery is more vivid than usual, less readily suppressed, and occupies a greater proportion of the subject's thought and time than formerly.

Abraham (1983) added additional phenomena, notably geometric pseudohallucinations, false perceptions of movement in the peripheral field, flashes of colour, intensified colours, and 'trailing phenomena' in which after-images remain immediately behind an object as it traverses the visual field. Symptoms were sometimes reported as long as 8 years after the last exposure to LSD. Common precipitants in Abraham's series were emergence into a dark environment, staring at a blank wall or the subsequent use of marijuana. Benzodiazepines were found to be useful in treatment.

Several explanations have been proposed to account for recurrences but none has been substantiated. Brain damage has been blamed, or the release of some stored metabolite, or neurophysiological changes in the mechanisms underlying imagery formation and suppression. Abraham (1982) has obtained evidence that LSD users are impaired on tests of

colour discrimination when examined an average of 2 years after their last exposure, and that those experiencing flashbacks are particularly affected. Further visual studies have shown depressed critical flicker frequencies and reduced sensitivity to light during dark adaptation in past users of LSD (Abraham & Wolf 1988). The tendency for recurrences to accompany periods of stress and anxiety has suggested that they may represent a form of conditioned response or learned reaction to anxiety. Psychodynamic theorists have viewed the recurrent imagery as representing screen images to conceal emotional conflict, or as symbolising the breakthrough of repressed ideas.

More recently, hallucinogen persisting perception disorder has been incorporated into the psychiatric diagnostic schedules, characterised by frequent flashbacks involving intense and intrusive visual recollection of prior hallucinations. Halpern and Pope (2003) have reviewed this field and identify the disorder as genuine but highly uncommon.

Solvent abuse

Solvent abuse is defined as the intentional inhalation of volatile substances to achieve an altered mental state. From initial recognition as a problem in the 1970s it continues to be a significant problem worldwide, with a striking variety of distinct solvents and delivery systems being described, according to availability and fashion. An influential classification by Balster (1998) defined three major classes of abused solvents: the volatile solvents, nitrous oxide and the alkyl nitrites. Volatile solvents include glues, thinners, fuels and anaesthetics, with street names such as 'air blast', 'disco-rama', 'hippie crack' and 'moon gas'. Nitrous oxide, known as laughing gas or 'shoot the breeze', can be obtained from diverted medical anaesthetics, but is also found in whipped-cream dispenser chargers (known as whippets). Volatile alkyl nitrites, known as 'poppers', 'snappers' or 'boppers', are also commercially available as Rush, Bolt, Thrust, Climax, Locker Room and tend to be associated with adult use, particularly in groups where men have sex with men.

Intriguingly, volatile solvent misuse is mainly a problem affecting young adolescents of school age, with a stable rate of 10% of adolescents admitting to having used solvents at some time (Williams & Storck 2007). In the UK it came to widespread recognition in the form of 'glue sniffing', carried out sporadically as a small-group activity, and prompted restrictions on the sale of a variety of previously readily available volatile products in 1999. As with all psychoactive drugs, use may be experimental or episodic. Serious complications are rare, although accidental injury while intoxicated and 'sudden sniffing death syndrome' related to cardiac toxicity are significant problems. Neurotoxic and systemic side effects are strongly associated with regular use over long periods. Detection of solvent misuse is a particular problem as initial effects are short-lived and the intoxicant itself is

volatile; however, as it may be exhaled, a characteristic odour may persist and findings such as perioral rashes, glitter or paint stains, and self-neglect provide clues.

Acute effects

Glue is commonly inhaled from a plastic bag ('bagging'), either nasally ('sniffing or snorting') or through the mouth ('huffing'), with depth of inhalation being adjusted for maximal euphoriant effect. Aerosols may be sprayed directly into the mouth or nose, a particularly hazardous procedure: 'dusting' refers to the direct application of computer cleaning products to the nose or mouth through the nozzle provided. Solvents are rapidly absorbed in the lungs, with immediate and brief effects. They act directly on the CNS through a variety of mechanisms identified in the action of alcohol or anaesthetics (Balster 1998), with a number of downstream effects on neurotransmitter systems, including promotion of GABA and opioid systems and inhibition of *N*-methyl-D-aspartate (NMDA) neurotransmission (for review see Bowen *et al.* 2006).

The subjective effects are a period of euphoria and exhilaration, known as the 'rush', setting in rapidly and accompanied by giddiness and disorientation. This phase may be prolonged for several hours by repeated inhalation, otherwise effects are brief and there is relatively rapid recovery. Nausea, slurred speech, dizziness, diplopia, ataxic gait and disorientation occur as the inhalant dose increases, and coma can supervene though uncommonly as this prevents the ability to repeat inhalation. Hallucinations may occur, chiefly in the visual modality and often frightening in nature. Spatial distortions, macropsia, micropsia and body image disturbances are commonly experienced. Disinhibition and feelings of omnipotence during the phase of intoxication may lead to risk-taking, accidents and aggressive antisocial behaviour. Amnesia for the events of the episode is common on recovery.

Nitrites differ pharmacologically from other inhalants, primarily causing vascular vasodilatation and smooth muscle relaxation. The sensations are of dizziness, tachycardia, light-headedness and skin warmth occurring within seconds, with effects wearing off in minutes. Nitrites are primarily inhaled to enhance sexual experience, with penile engorgement and anal sphincter relaxation (Romanelli *et al.* 2004).

Adverse consequences

The great majority of solvent misusers do not come before medical attention, and at the level of mild sporadic use appear usually to escape long-term physical damage. Nevertheless, it is a highly dangerous activity with a considerable number of acute deaths reported in occasional users, due to sudden sniffing death syndrome, inhalation of vomit or

suffocation from the plastic bag, aspiration, trauma, drowning or fire. Sudden sniffing death syndrome was described by Bass (1970) and arises from myocardial cell 'stabilisation', which increases the risk of cardiac arrhythmias, especially on sudden stress; this effect can be both acute and delayed, occurring hours after the period of use. Tolerance can develop if regular abuse persists over many months so that very large quantities come to be employed, whereas physical dependence by contrast appears to be uncommon.

The danger lies chiefly for those vulnerable individuals for whom inhalation becomes a regular and entrenched habit. A number of chronic complications, some serious, have now been reported, both with glue sniffing itself and with abuse of other solvents. These include cardiomyopathies, haematological complications such as aplastic anaemia, and renal toxicity. A range of CNS toxicities is seen, including toluene leucoencephalopathy, cerebellar ataxia, cranial neuropathy including optic neuropathy, encephalopathy both acute and chronic, and peripheral neuropathies. Much may depend on individual susceptibility to the chemicals involved.

Toluene leucoencephalopathy has been described since the early 1960s and is now a well-recognised syndrome, characterised by cerebellar ataxia, corticospinal tract dysfunction, brainstem signs and cranial neuropathies (Filley *et al.* 2004). An early example was reported by Grabski (1961) and followed up by Knox and Nelson (1966).

After some years of regular toluene inhalation, a 21-year-old man presented with confusion, inappropriate laughter and long periods of staring into space. He showed the classic titubating gait and intention tremors of cerebellar dysfunction. Over the years he became increasingly slowed and forgetful. On occasions when he stopped inhaling for several days the ataxia would remit considerably. Eight years later he was still abusing toluene and was ataxic, tremulous and emotionally labile.

Following on from these early reports a number of case series and case-control studies confirmed a characteristic neuropsychological syndrome regarded as prototypical of white-matter dementia (Filley *et al.* 2004). Characteristically, the dementia comprises inattention, apathy, memory dysfunction, visuospatial impairment, but with preservation of language. MRI shows, as indicated by the early air encephalograms, diffuse cerebral and cerebellar atrophy with characteristic white matter hyperintensities that correlate with extent of neuropsychological dysfunction (Yücel *et al.* 2008). Neuropathological examination at post-mortem shows cerebral and cerebellar myelin loss, perivascular macrophages containing debris, and gliosis in agreement with

findings in animal models that support astrocyte activation by toluene as the likely pathophysiological mechanism underpinning the white matter encephalopathy (Yamaguchi *et al.* 2002). During pregnancy, toluene abuse at high dose, rather than low-level environmental exposure, causes a constellation of teratogenic features known as fetal solvent syndrome, similar in nature to the fetal alcohol syndrome (Costa *et al.* 2002). Recent advances in MRI neuroimaging techniques, including diffusion tensor imaging, may improve early detection of toxicity and help resolve mechanisms of prognosis and recovery.

Petrol sniffing. In contrast to toluene leucoencephalopathy, less is known about the toxicity associated with petrol sniffing, a form of solvent abuse particularly associated with the most marginalised of groups in society. Intoxication is liable to continue for some hours after exposure, and prolonged or rapid inhalation may lead to a phase of violent excitement followed by coma. Chronic inhalation leads ultimately to loss of appetite and weight, neurasthenic symptoms, and muscular weakness and cramps. A special complication is encephalopathy due to the tetraethyl lead added to petrol, leading to a lead encephalopathy superadded to potential solvent encephalopathy that requires specific hospital management. In a follow-up study of 29 cases of neuropsychological impairment specifically occurring following petrol sniffing, Cairney *et al.* (2005) noted almost complete recovery with only the most severely affected showing residual signs of toxicity. However, given the example provided by toluene leucoencephalopathy, this finding should be regarded as provisional.

TOXIC DISORDERS

Certain metals and chemicals are the exogenous toxins considered in this section. Poisoning due to metals and other chemical compounds is largely the province of industrial medicine, but must also be borne in mind in occasional patients who present with psychiatric illness of uncertain aetiology. This section considers the role of environmental toxins in the development of neurodegenerative disorders *per se*, before considering the specific features of drug-induced toxicity and toxicity induced by lead, mercury, manganese, arsenic, thallium, organophosphorus compounds and carbon disulphide.

Environmental toxins and neurodegenerative disorders

Neurodegenerative disorders such as Alzheimer's disease and Parkinson's disease are increasingly recognised as involving environmental exposure to various toxins, in interaction with age and genotype. The clearest example of this model is provided by the designer drug 1-methyl-4-

phenyl-1,2,3,6-tetrahydropyridine (MPTP), which resulted in the development of acute parkinsonism, similar to idiopathic Parkinson's disease, in a group of heroin addicts in California (Langston *et al.* 1983). Since this observation, several epidemiological studies have indicated that different environmental agents, including pesticides, increase the risk of Parkinson's disease (Langston 2002; Steece-Collier *et al.* 2002). With regard to Alzheimer's disease, while the link with aluminium exposure continues to be controversial (Flaten 2001), the link with type 2 diabetes, a condition with substantial environmental determinants, is increasingly accepted (Nicolls 2004).

Toxic effects of other drugs

Many other drugs can produce toxic effects on the CNS and lead to psychiatric disturbance. The number involved is legion, and the variety of their effects too great to be discussed in detail here. Comprehensive reviews of drug toxicity are presented by Dukes (1992), and aspects of particular relevance to psychiatric practice are dealt with by Tornatore *et al.* (1987), Ciraulo *et al.* (1989) and Lipowski (1990). These cover the adverse reactions seen with steroids, insulin, narcotics, analgesics, hypnotics, anticonvulsants, tranquillisers, anticholinergic agents, antiparkinsonian drugs, rauwolfia alkaloids, antihypertensive drugs, digoxin, diuretics, antituberculous drugs, other antibacterial agents, androgens, estrogens and oral contraceptives. Only some of these are considered below. In a critical review of the association of psychoactive medications and delirium in hospitalised inpatients, Gaudreau *et al.* (2005) identified relatively few firm associations, with opioids, benzodiazepines and corticosteroids most robustly implicated.

Sometimes the toxic reaction is an idiosyncratic response to the drug given in normal therapeutic dosage, or to several drugs being prescribed in combination. For this reason it is essential to review the patient's current medication when dealing with psychiatric illnesses of obscure origin, and particularly when these take the form of acute organic reactions. Sometimes the cause is excessive self-medication, either in error or when the patient is addicted. The range of drugs surreptitiously abused tends to increase steadily. As a corollary, inadequate use of analgesic medications with concomitant breakthrough pain may be mistaken for anxiety, depression and addiction, so-called pseudoaddiction, which is now well recognised especially in palliative care settings (Porter-Williamson *et al.* 2003).

The commonest form of disturbance is an acute organic reaction of variable duration, usually with features typical of delirium and often with prominent hallucinations. Neurological and other systemic signs specific for the drug in question may be in evidence. However, some drugs are associated primarily with mood changes or psychotic reactions in clear consciousness, as described below.

The elderly are especially at risk of adverse drug reactions. Concomitant physical illness or incipient dementia will reduce the margins by which delirium is provoked. Common offending drugs include digoxin, minor and major tranquillisers, antihypertensives and diuretics. Hypnotics such as nitrazepam readily accumulate, leading to daytime confusion. Anticholinergic agents (antispasmodics, tricyclic antidepressants, phenothiazines and antiparkinsonian drugs) are particularly liable to induce confusion or memory impairment in the elderly (Potamianos & Kellett 1982). Anticholinergics have also been clearly incriminated as a major factor leading to postoperative delirium (Tune *et al.* 1981).

Antidepressants

Among psychotropic drugs, severe reactions may occasionally be seen with antidepressant medication or combinations of antidepressant drugs. These are reviewed by Connell (1968) and McClelland (1986). Minor degrees of disturbance are probably quite frequent; Davies *et al.* (1971) reported episodes of impaired memory and orientation in 13% of patients taking tricyclic antidepressant drugs, rising to 35% in those over 40 years of age. Withdrawal reactions may occasionally be seen when monoamine oxidase inhibitors, or more rarely tricyclic antidepressants, are stopped abruptly, with nausea, gastrointestinal upset, headache, anxiety and panic (Anon. 1986).

Lithium

Lithium can have serious effects on CNS functioning. A fine tremor, representing exaggeration of normal physiological tremor, must often be accepted, likewise some minor forgetfulness and lethargy. When such symptoms develop in patients on long-term lithium treatment, the possibility of induced hypothyroidism must be borne in mind (see Chapter 10). More marked symptoms – muscle fasciculation, coarse tremor, ataxia, incoordination or extrapyramidal signs – call for abrupt cessation of treatment. The development of confusion or impairment of consciousness constitutes a medical emergency; the severe encephalopathic reactions that then ensue sometimes prove to be irreversible or result in permanent brain damage. Increasing confusion is accompanied by seizures, cerebellar signs, marked generalised tremor or decerebrate rigidity. States of stupor or coma may be prolonged. For reasons that are unclear such reactions may sometimes set in despite normal serum concentrations of lithium (Spiers & Hirsch 1978; Newman & Saunders 1979). On recovery there may be long-lasting cerebellar and extrapyramidal deficits (Sellers *et al.* 1982; Schou 1984). Smith and Kocen (1988) have described two patients in whom the clinical picture closely resembled Creutzfeldt–Jakob disease, with rapid onset of dementia, rigidity and in one case myoclonic jerks. EEG closely supported such a diagnosis. In both cases discontinuation of lithium led to resolution of the

symptoms and EEG abnormalities over the course of 2–3 weeks.

The combination of lithium and haloperidol was specially incriminated by Cohen and Cohen (1974) in leading to severe reactions. Two of their patients were left with permanent parkinsonian–cerebellar deficits and dementia, and two with persistent dyskinesias. Loudon and Waring (1976) reported similar though milder reactions of this nature, and Spring (1979) described severe neurotoxic developments with the combination of lithium and thioridazine. Sometimes the same combination of drugs has been given previously without ill effect as in the following example.

A patient reported by Thomas (1979) had been maintained on lithium within the normal therapeutic range for many years. Haloperidol was then added on account of a hypomanic swing, in a dose of 1.5 mg three times per day. Two days later she developed gross extrapyramidal signs with marked rigidity and orofacial dyskinesia. She became severely confused and disorientated, and EEG showed diffuse slow waves. Both drugs were stopped, with gradual resolution of the extrapyramidal disturbance over the course of the next 3 months. However, she was left with persistent evidence of brain damage by way of disorientation and memory impairment. This patient had experienced the combination of lithium and haloperidol 3 years previously without adverse effect.

Such reports must be viewed in the context of the many patients treated safely on the same combinations of drugs. Nevertheless, close monitoring of the clinical situation and of serum lithium levels would seem essential whenever lithium is coupled with other neuroleptic agents. Episodes of sleep-walking have also been reported after adding neuroleptics to patients established on lithium; Charney *et al.* (1979) reported 10 examples, involving haloperidol, thioridazine, chlorpromazine and other neuroleptics, usually occurring within a few days of starting the second drug. Neurotoxicity has also been reported when lithium is given with carbamazepine, phenytoin or methyldopa (Beeley 1986).

Neuroleptic malignant syndrome

The extrapyramidal disorders associated with the phenothiazines and butyrophenones are described in Chapter 12. The neuroleptic malignant syndrome is a more recently recognised complication of such drugs, seemingly rare but of great importance in that it is not infrequently fatal. Reviews of the condition are provided by Caroff (1980), Cope and Gregg (1983), Addonizio *et al.* (1987) and Kellam (1987). It has been

described sporadically since the 1960s but the syndrome still lacks clear definition. Buckley and Hutchinson (1995) review its uncertain nosological status. An excess of cases has sometimes been described in patients below the age of 40 but the age range is wide. Males appear to be affected more commonly than females.

The patient develops severe extrapyramidal rigidity and akinesia, usually setting in abruptly or over the course of several days. Pyrexia is a characteristic accompaniment, along with autonomic disturbances by way of sweating, sialorrhoea, tachycardia, hyperventilation and labile blood pressure. Muscular rigidity is the cardinal feature, but may be accompanied by tremor, oro-bucco-lingual dyskinesias and sometimes dysphagia and dysarthria. Fluctuating impairment of consciousness can lead to confusion, stupor or coma. Agitation is common and may be severe. Dehydration and prostration can become extreme. Common laboratory findings include a leucocytosis, raised creatine phosphokinase activity and abnormal liver function tests, but these are not invariable. EEG sometimes shows diffuse slowing but is usually normal. CT is uninformative. The picture may be mistaken for encephalitis or meningitis, but CSF examination is negative. Catatonia may be diagnosed on account of the stupor, posturing or waxy flexibility. Anticholinergic intoxication should be considered in the differential diagnosis. Death is estimated to occur in up to 20% of cases, usually from cardiorespiratory failure, pneumonia or renal failure secondary to rhabdomyolysis and myoglobinuria.

The syndrome has been reported in association with butyrophenones, phenothiazines and thioxanthenes, though perhaps most commonly with haloperidol and depot fluphenazines. It sets in usually within the first 2 weeks of treatment. It may begin shortly after the first dose, though a puzzling feature is its occasional development after many months on the drugs. Earlier courses of the identical drugs may have been given without adverse effect. In a small but important subgroup an identical syndrome has developed in parkinsonian patients when antiparkinsonian medications such as levodopa or amantadine are withdrawn (Kellam 1987). Rare examples have been reported following lithium, metoclopramide, carbamazepine, desipramine, dothiepin, tetrabenazine and other non-neuroleptics (Buckley & Hutchinson 1995).

Medically ill psychiatric patients appear to be at increased risk, many examples developing in patients with dehydration, malnutrition or concomitant neurological disease (Sternberg 1986). Indeed Levinson and Simpson (1986) have questioned the unitary nature of the syndrome, suggesting that a number of examples merely represent extrapyramidal reactions complicated by fever due to remediable medical conditions. Dehydration with electrolyte imbalance and infections such as pneumonia appeared to be the factors most often responsible.

Treatment consists of the withdrawal of all neuroleptic medication immediately the condition is suspected, along with intensive supportive measures to maintain respiratory, renal and cardiovascular function. Dehydration or electrolyte imbalance must be remedied, and a thorough search made for infections and other medical conditions that may be complicating the picture. Active cooling measures may be required. Benefit has been reported from treatment with dantrolene sodium, a peripheral muscle relaxant, and the dopamine agonist bromocriptine (Granato *et al.* 1983; Miyasaki & Lang 1995). Electroconvulsive treatment has sometimes been found to be rapidly beneficial, although obviously this must be undertaken with care (Davis *et al.* 1991). From Davis *et al.*'s review such treatment appears to be safe, with the proviso that neuroleptics are discontinued beforehand.

The disorder usually lasts for 5–10 days after stopping the drugs, or rather longer with depot preparations. Resolution is typically complete in those who recover, although occasional patients are left with neurological residua (Miyasaki & Lang 1995). When treatment of the original psychiatric disorder continues to be necessary, alternative drugs such as carbamazepine or lithium should be tried. If it is essential to reintroduce phenothiazines, those with low potency should be given initially. Careful monitoring of blood pressure and temperature will then be necessary, with vigilance if extrapyramidal rigidity should develop. There are indications that 'rechallenges' with neuroleptics are in fact often safely accomplished, provided a gap of at least 2 weeks is left after resolution of the syndrome (Rosebush *et al.* 1989). Clozapine should be considered when conventional neuroleptics cannot be tolerated (Weller & Kornhuber 1992).

Dopamine receptor blockade in the basal ganglia or hypothalamus has been postulated as the cause, though with little direct supportive evidence. However, significantly decreased levels of homovanillic acid, the major metabolite of dopamine, have been found in the CSF both during active phases and after recovery from the syndrome (Nisijima & Ishiguro 1990). Some evidence also points to serotonergic involvement (Buckley & Hutchinson 1995). At post-mortem, no specific abnormalities have yet been discovered.

Attention has been drawn to certain similarities between the condition and the 'fatal catatonia' of the pre-neuroleptic era (Caroff 1980; Kellam 1987). Some examples of adverse reactions to the combination of lithium and haloperidol may also represent variants of the syndrome, particularly the cases reported by Cohen and Cohen (1974) where extrapyramidal dysfunction was accompanied by fever, leucocytosis and elevated serum enzymes. On present evidence the condition would seem to represent an idiosyncratic reaction to neuroleptic medication, although it remains possible that this may merely have served as a trigger to some largely independent pathogenic process.

Withdrawal effects

Withdrawal effects must be considered where drugs with a depressant action on the CNS are concerned. Drugs other

than alcohol or barbiturates can lead to severe withdrawal phenomena including epileptic fits, hallucinations and periods of delirium. Such pictures have been reported for glutethimide (Doriden) and ethchlorvynol (Placidyl) in patients admitted to hospital for investigation of long-standing intermittent confusion (Lloyd & Clark 1959; Hudson & Walker 1961). Similar results may follow withdrawal from paraldehyde, meprobamate, methaqualone (Mandrax) and carbromal (Granville-Grossman 1971). The withdrawal effects that can be seen with benzodiazepines are described earlier under Benzodiazepines/Withdrawal effects.

Analgesics

Chronic analgesic abuse may readily cause diagnostic confusion. Bizarre behaviour and hyperventilation may lead to a mistaken diagnosis of hysteria. When consciousness is severely impaired diabetic coma may be suspected. Greer *et al.* (1965) reported examples of chronic salicylate intoxication producing pictures of confusion, amnesia, agitation, stupor and coma. Some patients were hallucinated, paranoid and combative. Hyperventilation and tinnitus were important signs, also coarse irregular tremors of the hands and ataxia of gait.

Murray *et al.* (1971) drew attention to another possible hazard of chronic analgesic abuse. Of eight patients who had consumed very large doses of compound analgesics containing phenacetin, four showed definite evidence and two possible evidence of dementia. Neuropathological studies of the brains of nine other analgesic abusers showed a surprisingly high frequency of histological changes typical of Alzheimer's disease even though cerebral atrophy was absent. These interesting findings merit further investigation.

Steroid therapy

Mood changes accompanying steroid therapy more often consist of mild elation than depression, and are much commoner than confusion or delirium (Granville-Grossman 1971). The elation and social activation seen while on steroids may be replaced by depression when the drugs are withdrawn (Carpenter & Bunney 1971). More florid reactions have been reported in up to 10% of patients given steroids in large dosage: excited elated behaviour, intense anxiety with panic attacks, severe depression, or transient psychoses with perceptual abnormalities, hallucinations, derealisation and paranoia. Such reactions are often deeply alarming to the patient, but generally subside within a few weeks when the drugs can be withdrawn.

Their determinants will often be complex when the steroids are given for conditions that implicate the CNS. However, Hall *et al.* (1979) restricted attention to the psychoses seen in patients in whom there was no reason to suspect a cerebral lesion. They found that the clinical pictures defied formal classification, often representing a complex admixture of affective, schizophreniform and organic features.

Moreover, a single episode in a given patient could show a great variety of symptoms from one moment to another, and little was characteristic except this changeability. A common constellation of symptoms was emotional lability, anxiety, distractibility, pressured speech, insomnia, perplexity, agitation, hypomania, auditory and visual hallucinations, delusions, intermittent memory impairment, mutism and body image disturbance. The onset was usually within 3 weeks of the start of treatment, mostly within 5 days, and response to phenothiazines was excellent. EEG changes of a non-specific type commonly accompanied the disturbances, reverting to normal on recovery. There was no evidence that a history of previous psychiatric illness was a predisposing factor.

Other drug reactions

An important group of drugs are those which produce mood changes or psychotic reactions without evidence of confusion or impairment of consciousness. With reactions of this type it is less likely that the essentially 'toxic' nature of the disturbance will be appreciated. Rauwolfia alkaloids were an early example, leading to severe depressive mood changes unaccompanied by organic mental symptoms. The rauwolfia reaction may develop only after several weeks or months on the drug, and has been attributed to a fall in cerebral monoamines.

Heavy metals and other chemicals

Heavy metals are chemical elements with a specific gravity at least five times that of water. There are at least 23 such elements. The heavy elements most implicated in human poisoning are lead, mercury, arsenic and cadmium. Some heavy metals such as zinc, copper, iron and manganese are required in the body in small amounts but are toxic in large quantities.

Lead

Lead is found in cosmetics, plastics, batteries, insecticides, pottery glaze, soldered pipes and paint. Modern building specifications prevent a previous major source of lead exposure, namely drinking water from old lead-piped plumbing systems. Older buildings remain a risk. Domestic water supplies remain a risk in areas where the water is soft, and some outbreaks have been traced to beer or cider stored overnight in lead pipes. Industrial causes have been greatly reduced as a result of stringent precautions, but a risk exists in the following occupations: painting, plumbing, ship building, lead smelting and refining, brass founding, pottery glazing, vitreous enamelling; the manufacture of storage batteries, white lead, red lead, rubber, glass and pigments; and among compositors who handle type metal. The list is important because a history of exposure is often the crucial factor in arousing suspicion of the disorder. Overt lead poisoning is

now a great deal rarer than during the early part of the twentieth century. 'Subclinical' lead poisoning refers to low-level lead exposure, particularly in children, who are especially vulnerable because they absorb more lead than adults due to their developing nervous system. A blood lead concentration of 10 µg/dL or higher in children is cause for concern. In 1984, the Centers for Disease Control and Prevention estimated that 3–4 million American children had unacceptably high levels of lead in their blood. A recent report evidences a progressive decline in the overall prevalence of a blood lead level of 10 µg/dL or more in US children aged 1–5 years from 8.6% (1988–1991) to 1.4% (1992–2004). The authors found that 55% of children overall have a blood lead level between 1 and <2.5 µg/dL but non-Hispanic black US children remain at highest risk. Risk factors for higher blood lead levels are residing in older housing, poverty, and being a child in a younger age group (Jones *et al.* 2009). A number of behavioural effects are recognised complications of raised lead levels, including impaired cognitive performance.

Needleman *et al.* (1990) found that adolescents who had high dentine lead levels in childhood 10 years earlier had poorer hand–eye coordination, longer reaction times and slower finger-tapping than children who had low dentine lead levels in childhood. Bellinger *et al.*'s (1992) prospective study indicated that higher blood lead levels at age 24 months were significantly predictive of lower global scores on the Wechsler Intelligence Scale for Children (WISC)-R and measures of educational attainment at age 10. Even over the range 0–25 µg/L, a 10-µg increase in blood lead at 24 months was associated with a 5.8-point reduction in WISC IQ at 10. Tong *et al.*'s (1996) follow-up of children from a lead smelting town in Australia has lent strong support to this finding. Seeber *et al.* (2002) detected cognitive deficits with average blood lead levels between 370 and 520 µg/L. The unborn fetus and the elderly are also at risk of neuropsychiatric complications.

The principal manifestations include abdominal colic, 'lead neuropathy' and 'lead encephalopathy'. Lassitude is almost invariably the earliest symptom. Aching in joints and limbs is also common. Gastrointestinal disturbances then appear, with anorexia, constipation and attacks of severe intestinal colic. The child is pale and often irritable. Acute phases of disturbance tend to be precipitated by intercurrent infection or other sources of acidosis which mobilise lead from the bones. 'Peripheral neuropathy' was formerly common in adults but has always been rare in children. It is now very rare in both. It is unique in being a purely motor disturbance, perhaps with the primary effect on the muscles themselves, although ultimately the nerves are involved as well. The muscles chiefly affected are those most used, resulting in the classic picture of wrist drop and paralysis of the long extensors of the fingers. Less commonly there is weakness and wasting of the shoulder girdle muscles or of the dorsiflexors of the foot. Lead encephalopathy is the most serious

manifestation. In adults it may present with episodes of delirium, often in association with fits. During crises the blood pressure is elevated. In chronic encephalopathy the patient is dull, with poor memory, impaired concentration, headache, trembling, deafness or transitory episodes of aphasia and hemianopia (Hunter 1959). However, the most pronounced manifestations are seen in children, and cerebral involvement is reported in about half of those affected. The encephalopathy may sometimes set in very rapidly. The intracranial pressure rises abruptly, with headache, projectile vomiting, visual disturbances and severe impairment of consciousness. Convulsions and muscular twitching are common, and acute delirium may lead on to coma. Ocular and limb pareses may develop. Papilloedema is often seen, and meningeal irritation may cause neck stiffness and head retraction. The CSF is under increased pressure, the protein is raised and a moderate pleocytosis may be found. Death can result from medullary compression.

Diagnosis

In the diagnosis of lead poisoning there is no one sign which is pathognomonic. A lead line on the gums may be produced by subepithelial deposits of lead sulphide, especially when the teeth are carious. However, this is rare in children. Anaemia is always present and usually accompanied by basophilic stippling of the erythrocytes. In young children, radiography of the long bones shows a dense band in the lines of provisional calcification. Repeated examination of the blood and urine may reveal a raised lead content, but single readings can be misleading with falsely high or low results. Coproporphyrins are increased in the urine. Lead encephalopathy should be considered in children who develop fits of obscure origin, and when headache and papilloedema are discovered without obvious cause. Anaemia in association with colic or peripheral neuropathy should similarly raise suspicion. Diseases that may be simulated include encephalitis, cerebral tumour, tuberculous meningitis, uraemia and hypertensive encephalopathy.

Treatment

Most of the lead is held in storage in the bones, and as a temporary measure storage can be promoted by giving calcium lactate and extra milk in the diet. Chelating agents are used to promote the urinary excretion of lead and disodium calcium ethylenediaminetetra-acetate (calcium versenate, EDTA) can be given parenterally. Lead replaces the calcium in the compound and the circulating unionised chelate is excreted by the kidneys. Symptoms are rapidly relieved because the chelate is much less toxic than the ionised metal in body fluids. In consequence, chelating agents have been regarded as life-saving in the management of acute lead encephalopathy. Meso-2,3-dimercaptosuccinic acid ('succimer'), an analogue of dimercaprol, has been employed as an oral chelating agent with low toxicity.

Outcome

The risk of permanent intellectual disablement is considerable among the survivors of lead encephalopathy. Children may be left with mental retardation, cerebral palsy, fits, or blindness due to optic atrophy. Perlstein and Attala (1966) reviewed a large group of 425 children who had suffered lead poisoning, finding permanent sequelae in 39%. This rose to 82% among those who had presented with encephalopathy.

Cerebral pathology

The cerebral manifestations have been attributed to a combination of intense cerebral oedema and vascular changes. There is proliferation of the endothelium of small blood vessels, sometimes with occlusion of the lumen, and the development of perivascular nodules of hypertrophied glial cells. Cerebral ischaemia may result from the acute rise in intracranial pressure and lead to cerebral atrophy. In chronic cases the meninges become fibrosed and hyperplastic, and arachnoiditis obstructs the flow of CSF (Akelatis 1941). Internal hydrocephalus is often marked in patients who show residual cerebral impairment.

Mercury

Mercury is both a unique element that has no essential biological function and a ubiquitous environmental toxin that causes a wide range of adverse health effects in humans. It is liquid at room temperature, is 13.6 times heavier than water, and its vapour pressure at 20°C is 0.16 Pa (Tennent 1971). Mercury and zinc are easily volatile metals compared with, for example, magnesium and iron. Mercury has been used in mercury switches, thermostats, thermometers and other instruments. Its ability to amalgamate with gold and silver has been used in mining these precious metals, and is also used as a dental restorative. Its toxic properties have been exploited for medicines, preservatives, antiseptics and pesticides (Gochfeld 2003). There are three forms of mercury from a toxicological point of view, each with its own profile of toxicity: inorganic mercury salts, organic mercury compounds, and metallic (or elemental) mercury. Inorganic mercury salts are water soluble, irritate the gut and can cause severe kidney damage. Organic mercury compounds are fat soluble, can cross the blood–brain barrier and cause neurological damage. Metallic mercury poses two dangers. It can vaporise at room temperature so that poisoning can occur even if mercury metal is spilled in crevices or cracks in the floorboards. Metallic mercury can be biotransformed into organic mercury by bacteria, for example, in lakes. This can be passed along the food chain and eventually to humans (Langford & Ferner 1999).

Chronic mercury poisoning was commoner in former times as a hazard among workers involved in recovering the metal from the ore and in chemical workers, thermometer

makers and photo engravers. Groups of cases were reported among fingerprint experts employing a mercury and chalk mixture (Agate & Buckell 1949) and among repairers of direct current electric meters (Bidstrup *et al.* 1951). Mercury was also extensively employed in the felt hat industry, where the toxic effects no doubt contributed to the epithet ‘mad as a hatter’ and to Lewis Carroll’s choice of the hatter in *Alice in Wonderland*. Warkany and Hubbard (1951) discovered that the mercury contained in teething powders was the common cause of acrodynia (pink disease) in infants and young children.

Lead, mercury and arsenic exposures represent the most common causes of toxic metal poisoning. In 1997, 3596 cases of mercury heavy metal poisoning were reported by the American Association of Poison Control Centers (Patrick 2002). The major forms of exposure are mercury vapour, the elemental mercury content of dental amalgam, and methylmercury compounds. Mercury vapour emitted from both natural and anthropogenic sources is globally distributed in the atmosphere. It is returned as a water-soluble form in precipitation and finds its way into bodies of fresh and ocean water. Land run-off also accounts for further input into lakes and oceans. Inorganic mercury present in water sediments is subject to bacterial conversion to methylmercury compounds, which are bioaccumulated in the aquatic food chain to reach the highest concentration in predatory fish (Clarkson 1997). The general population does not face a significant health risk from methylmercury, although certain groups with high fish consumption may attain blood levels associated with a low risk of neurological damage to adults. Since there is a risk to the fetus in particular, pregnant women are advised to avoid a diet high in the intake of certain fish, such as shark, swordfish and tuna. Fish such as pike, walleye and bass taken from polluted fresh waters should also be avoided (Jaerup 2003). In addition, Salonen *et al.* (1995) reported evidence to suggest that a high intake of mercury from non-fatty freshwater fish was associated with an excess risk of acute myocardial infarction and death from coronary heart disease in eastern Finnish men, perhaps due to the promotion of lipid peroxidation by mercury. Several studies since have reported statistical associations between cardiovascular disease and mercury but conclusions about cause and effect lack evidence because of the multiple risk factors for cardiovascular disease (Clarkson *et al.* 2003). The European Environment Agency (EEA) suggests that blood concentrations of mercury below 5.8 ng/ml will avoid adverse effects, but cautions that people who eat fish contaminated by methylmercury have been found to have levels very close to this at 5.6 ng/ml (2002). The balance of published reports suggests that the CNS and kidneys remain the key targets of mercury toxicity.

Elemental mercury vapour accounts for most occupational and accidental exposures by inhalation. Mercury is readily absorbed after inhalation. Mercury can be an indoor

air pollutant as well as an industrial emission with resulting ambient air pollution (Goldman & Shannon 2001). Currently, mercury vapour concentrations greater than 0.01 mg/m^3 are considered unsafe (Moienafshari *et al.* 1999). Fetuses are considered the most sensitive subpopulation because of the vulnerability of the developing nervous system. A level of $0.1 \text{ } \mu\text{g/kg}$ body weight per day has been reported as a scientifically justified (safe?) level of methylmercury exposure for maternal–fetal pairs (Mahaffey 2000).

Dental amalgam, which consists of about 50% metallic mercury, has been used for over 150 years in dental practice. Mercury is continuously released from dental amalgam and absorbed by several body tissues (Mutter *et al.* 2004). Whether the amounts released are sufficient to cause significant toxicity is controversial (Null & Feldman 2002). It has been suggested that although the mercury vapour generated during removal of amalgams does cause a transient increase in the patient's mercury levels in tissue fluids, biochemical assays demonstrate that the increase is too small to have an adverse impact on organ systems, true also even when patients have all their amalgams removed in a single session (Osborne & Albino 1999). Patients with so-called 'amalgam illness' are thought to be exhibiting psychogenic disorders in a large number of cases, including a high prevalence of somatisation (Langworth 1997). Dentists occupationally exposed to mercury have not been shown to suffer harmful reproductive or other systemic health effects (but cognitive changes have been seen) provided proper mercury hygiene is used (Wahl 2001).

Mercury's several different forms, and the subtlety of its chemical effects at chronic low-level exposure, make the diagnosis of mercury toxicity difficult to establish. Diagnosis is also made difficult because of the lack of specific signs. A high index of suspicion is necessary when patients present with a combination of behavioural and personality changes, movement disorder, memory problems, unusual rashes or neuropsychological deficits. It is only in cases involving a knowledge of mercury that appropriate historic information is obtained, and clinical suspicions confirmed by establishing toxic levels of mercury in blood and urine (Johnson 2004).

Clinical manifestations

Physical symptoms include stomatitis, spongy bleeding gums and excessive salivation. A coarse tremor may develop in the hands, face and tongue, characteristically interrupted by coarse jerking movements (hatters' shakes). A sensorimotor peripheral neuropathy is common, sometimes with prominent sensory ataxia, also varying degrees of visual field constriction.

Psychological symptoms are often an early manifestation. In particular a constellation of symptoms known as 'erythism' has been repeatedly noted. In this the sufferer is nervous, timid and shy, blushes readily and becomes em-

barrassed in social situations. He objects to being watched and seeks to avoid people. He becomes irritable and quarrelsome, sometimes to the extent that he is obliged to give up work. Such symptoms are usually accompanied by lassitude, tremulousness, ataxia and some degree of impairment of intellectual capacity.

A detective sergeant of 45 was trained in fingerprint work and sent to a division where he investigated up to 300 crimes per year. During this time he became a 'nervous wreck', could not hold a cup without spilling it, and found court appearances acutely distressing because he could not stand still or answer questions without embarrassment. During the early war years the crime rate declined and his symptoms improved, but they worsened again immediately the crime rate rose in the postwar period. On examination he showed a marked tremor and several teeth were loose.

Bidstrup *et al.* (1951) found definite evidence of erythism in 10 and probable evidence in 8 of 161 men engaged in mending direct current electric meters.

One employee had noticed tremor of his hands for a year and had become irritable, short-tempered and easily embarrassed. He had developed a stammer for the first time in his life. A few months later he became unsteady on his feet and his whole body developed a tremor. His writing became almost illegible. He was ultimately diagnosed as suffering from multiple sclerosis. At this point he read in the daily paper about the above findings in the Lancashire Constabulary and told his general practitioner that he too handled mercury. Six months after transfer to another job he had recovered completely.

Kark *et al.* (1971) report another example with prominent neurological symptoms.

A man who had worked for 2 years extracting mercury from batteries showed a gradual decline in memory and loss of interest, becoming less talkative and active. He developed gingivitis, decreased visual acuity and insomnia. Tremor ultimately made eating and drinking impossible, and he was virtually unable to stand on account of titubation and truncal ataxia. On examination he showed dysarthria, constricted visual fields, and diminished acuity of both hearing and vision. There were constant choreiform movements of the face and fingers. EEG showed diffuse theta activity and the air encephalogram revealed cerebral atrophy. He recovered slowly on treatment with chelating agents.

Neuropsychological testing has shown identifiable deficits in persons chronically exposed to mercury, often persisting for many years. For example, Ngim *et al.* (1992) found that dentists with a history of contact with mercury vapour were significantly poorer than controls on tests of motor speed, visual scanning, visuomotor coordination and memory. Performance correlated inversely with the cumulative dose of exposure. None showed overt toxic signs but their blood mercury levels were raised. Hartman (1988) and O'Carroll *et al.* (1995) review studies on mercury miners and plant workers that have shown impairment of motor coordination, reaction time and short-term memory. O'Carroll *et al.*'s own patient suffered exposure while cleaning a tank containing phenylmercury ammonium acetate (which releases inorganic mercury in the body) and was chronically disabled thereafter by muscle spasms, shakiness, anxiety and depression. Psychological testing 3–4 years later showed marked and specific deficits in attention and concentration, with performance well below expectation on verbal fluency, Trail-making and Stroop tests and on the Paced Auditory Serial Addition Test (PASAT). MRI showed no abnormality, but SPECT revealed focal hypermetabolism in the posterior cingulate cortex.

Acrodynia is a serious disease of infants and young children. The hands and feet are reddened with desquamation of the skin, itching, burning and evanescent rashes. In severe cases the hair and even the nails may be lost. The child is restless and miserable, showing periods of apathy alternating with extreme irritability. Anorexia, insomnia and photophobia are prominent. On examination there is hypotonia with diminished tendon reflexes and peripheral sensory loss. There is a tachycardia and the blood pressure is raised. The cause was unknown, although a toxic agent had long been suspected. In 1951, Warkany and Hubbard found mercury in the urine in a large number of cases, and proposed that exposure to mercury in hypersensitive infants was the responsible factor. This has since been well established (Dathan 1954), the source being mainly from teething powders, worming pills, ointments or nappy powders. Fortunately, the condition is now very rare indeed.

Organic mercury compounds

Organic mercury compounds are associated with marked neurological and psychiatric disturbances, especially the ethyl and methyl derivatives, which are used in the manufacture of fungicides. From time to time certain accidents have resulted in large outbreaks of poisoning with a heavy mortality. In the Minamata Bay epidemic in Japan, 83 persons were affected, most patients dying or suffering permanent severe disability (Kurland *et al.* 1960). Inorganic mercury derived from industrial processes had been discharged into rivers, methylated by aquatic microorganisms, and eaten by fish which then became poisonous. More recently, Amazonian riverside communities in Brazil have been

affected as a result of mercury used in the course of gold mining (Anon. 1992). In Iraq several outbreaks resulted from the distribution of grain treated with fungicides, intended for planting but made into bread by mistake. In the 1972 epidemic, 6500 persons were admitted to hospital and there were 459 deaths (Bakir *et al.* 1973).

Sensory disturbances are in the foreground, with numbness of the hands, deafness, blurred vision and narrowing of the visual fields progressing to blindness (Hunter 1978). Ataxia and dysarthria may be severe, often in association with sore gums and salivation. Involuntary movements and convulsions are common. Mental dullness is accompanied by restlessness, progressing over the course of weeks or months to coma. Many cases are fatal. At post-mortem, selective cortical damage is seen in numerous areas, with neurone loss, porosity of the underlying white matter and swelling of oligodendrocytes (Hay *et al.* 1963). Extensive spongiosis of the cortex may occur in childhood cases (Takeuchi *et al.* 1979). Severe destruction may also be seen in the cerebellum, basal ganglia and calcarine region (Feldman 1982).

Manganese

Manganese is an essential trace element, functioning as a cofactor in many enzymatic reactions in both animals and humans, but which, in excess, can cause irreversible nervous system damage. Manganese is supplied to the brain via both the blood–brain and blood–CSF barriers. Transferrin may be involved in manganese transport into the brain. A large portion of manganese is bound to manganese metalloproteins, especially glutamine synthetase in astrocytes. Manganese may be present in synaptic vesicles in glutamatergic neurones, and manganese released into the synaptic cleft may influence synaptic neurotransmission (Takeda 2003).

Manganese is a ubiquitous constituent of the environment, comprising about 0.1% of the earth's crust. For the general population food is the most important source of manganese, with daily intake ranging from 2 to 9 mg. Absorption from the gastrointestinal tract occurs as the divalent and tetravalent forms. Homeostatic mechanisms limit absorption of manganese from the gastrointestinal tract. Elimination of manganese occurs primarily by excretion into bile (Barceloux 1999). The CNS, and the basal ganglia in particular, is an important target in manganese neurotoxicity. Manganese neurotoxicity has been known for more than 150 years since Couper in 1837 described a syndrome in Scottish workers exposed to high levels of dust while grinding black oxide of manganese at a chemical industry. Since then the syndrome has been described in several groups of workers and manganese poisoning remains a predominantly occupational disease.

It occurs in manganese ore workers and those involved in steel manufacture, dry battery manufacture, bleaching and electro-welding. Despite the large number of people at risk,

manganese poisoning is relatively rare and it is probable that a large quantity can be absorbed over a long period of time before harmful effects are produced. Individual sensitivity also appears to be important in that some subjects exposed for an equally long period show no ill effects. The chief route of entry is inhalation of the dust, fumes or vapour. Since 1976 the organomanganese compound methylcyclopentadienyl manganese tricarbonyl (MMT) has been used as an anti-knock agent and octane enhancer in unleaded gasoline, increasing the atmospheric emission of MMT combustion products from the tailpipe of vehicles, principally manganese phosphate, manganese sulphate and manganese phosphate/sulphate mixtures. Animal exposure studies (oral administration) indicate that brain manganese concentrations are significantly higher in exposures to manganese phosphate and manganese phosphate/sulphate mixtures, with neurobehavioural consequences (Normandin *et al.* 2004). There remains uncertainty as to whether the small increase in manganese contamination resulting from use of MMT could have neurotoxic effects in humans as a consequence of inhalation exposure (Normandin *et al.* 2002).

Manganese contamination also occurs as a consequence of the use of the contrast agent mangafodipir trisodium in nuclear magnetic resonance diagnostic imaging. The manganese released from mangafodipir trisodium is initially sequestered by the liver for first-pass elimination, which allows enhanced contrast. Human manganese deficiency is rare but has been reported in patients on parenteral nutrition and in micronutrient studies (Crossgrove & Zheng 2004). In mammalian cells toxic doses of manganese cause DNA damage and chromosome aberrations. Large amounts of manganese affect fertility in mammals and are toxic to the embryo and fetus. The fungicide MANEB and the contrast agent mangafodipir trisodium can also be embryotoxic, the latter only at doses much higher than those employed clinically (Gerber *et al.* 2002). Learning difficulties have been tentatively linked to the use of infant feeding formulas with high manganese content (Cawte 1985).

Clinical manifestations

The early manifestations usually develop insidiously with headache, asthenia, torpor and hypersomnia. Impotence is common. Psychological abnormalities then become pronounced and may first draw attention to the disorder. There have been reports of marked emotional disturbances in up to 70% of cases, especially episodes of persistent and uncontrollable laughter and crying (Fairhall & Neal 1943). There may be strong impulses to run, dance, sing or talk which the patient finds difficult to resist. Impulsive acts and stupid crimes are a special risk in the early phases (Penalver 1955). Other abnormalities include forgetfulness, mental dullness, marked irritability and outbursts of aggression. Neuropsychological assessment in refinery workers has shown constructional apraxia, correlating significantly with levels of

exposure to manganese dust (Brown *et al.* 1991). Very occasionally an acute psychotic picture is seen, with severe excitement, agitation, hallucinations and delusions (Abd El Naby & Hassanein 1965).

Parkinsonism develops later with typical mask-like facies, slow monotonous speech and slowing of voluntary movements. Nocturnal leg cramps are a prominent feature. Fine tremor or gross rhythmical movements develop in the hands, limbs and trunk. The gait becomes typically parkinsonian with retropulsion and propulsion. A characteristic 'cock-step' gait has been described, a peculiar broad-based slapping walk with the legs held stiffly on tip-toe and wide apart. On examination muscular rigidity is found, with increased reflexes and ankle clonus. Cerebellar deficits may also be present. Sensory disturbances are rare. Chronic headache and severe insomnia may accompany the neurological developments.

Severe examples have been misdiagnosed as paralysis agitans, Wilson's disease, postencephalitic parkinsonism or multiple sclerosis. Wilson's disease may be closely simulated since liver damage may also be present. Manganese preferentially damages areas of the brain different to those affected in Parkinson's disease. In Parkinson's disease the pathology is a result of dopamine neurones in the substantia nigra pars compacta, whereas in manganese-induced parkinsonism the damage is localised to the pallidum and striatum. The positive response to levodopa in patients with Parkinson's disease also distinguishes it from manganese-induced parkinsonism in which the response is poor or nil. MRI abnormalities indicative of degeneration of the striatum predicts the evolution of atypical parkinsonism rather than Parkinson's disease. Striatal fluorodopa uptake on PET is consistently reduced in Parkinson's disease (especially in the posterior putamen) but normal in parkinsonism induced by manganese toxicity. These features all help to distinguish Parkinson's disease from magnesium-induced parkinsonism and permit the correct diagnosis to be established (Olanow 2004).

Removal from exposure at an early stage usually allows considerable recovery to occur. The psychological symptoms resolve quickly but disturbance of speech and gait may persist. In well-established cases the neurological disabilities may prove to be irreversible and patients are left permanently disabled. A considerable number have been observed to worsen neurologically even after removal from exposure (Abd El Naby & Hassanein 1965). Treatment with levodopa may sometimes improve the motor abnormalities (Huang *et al.* 1989).

At post-mortem, the basal ganglia are found to be mainly affected, with cell loss, gliosis and shrinkage. This is most marked in the globus pallidus. The thalamus may also be involved. Diffuse changes are found elsewhere including the cerebral cortex and brainstem, and slight generalised cortical atrophy may be seen (Canavan *et al.* 1934). In advanced

cases the peripheral nerves and muscles may show degenerative changes (Penalver 1955).

The mechanism of neurotoxicity relates to mitochondrial dysfunction, depletion of levels of peroxidase and catalase, and catecholamine biochemical imbalances following manganese exposure. The site specificity of the pathology (basal ganglia) and the nature of the cellular damage caused by manganese have been attributed to its capacity to produce cytotoxic levels of free radicals. There is recent evidence at a molecular level of an aetiological relationship between oxidative stress and manganese-related neurodegeneration (HaMai & Bondy 2004).

At a cellular level, increasing evidence suggests that astrocytes are a site of early dysfunction and damage; chronic exposure to manganese leads to selective dopaminergic dysfunction, neuronal loss, and gliosis in basal ganglia structures together with characteristic astrocytic changes known as Alzheimer type II astrocytosis. Astrocytes possess a high-affinity high-capacity specific transport system for manganese that facilitates its uptake and sequestration in mitochondria, leading to disruption of oxidative phosphorylation. In addition, manganese causes a number of other functional changes in astrocytes, including impairment of glutamate transport, alterations in the glycolytic enzyme glyceraldehyde 3-phosphate dehydrogenase, and increased densities of binding sites for the peripheral-type benzodiazepine receptor (a class of receptor predominantly localised to mitochondria of astrocytes and involved in oxidative metabolism, mitochondrial proliferation and neurosteroid synthesis). Such effects can lead to compromised energy metabolism, resulting in altered cellular morphology, production of reactive oxygen species and increased extracellular glutamate concentration. These consequences may result in impaired astrocyte-neuronal interactions and play a major role in the pathophysiology of manganese neurotoxicity (Normandin *et al.* 2002).

Arsenic

Arsenic poisoning is encountered in the ore-refining industry, the fur industry, and in the manufacture of glass, insecticides and herbicides. Acute poisoning results in vomiting, diarrhoea and violent abdominal cramps. Headache, delirium and fits develop, and coma and death may follow within 2 or 3 days.

In chronic arsenic poisoning the picture is different. Early signs include dermatitis, conjunctivitis, lacrimation and coryza. Keratosis and skin pigmentation may be extensive, with characteristic white lines across the nails (Mee's lines). Anorexia and weight loss are common, but the abdominal cramps and diarrhoea of acute poisoning are often absent. Headache and vertigo are accompanied by apathy, drowsiness and impairment of mental acuity. At this stage the mental changes can be the leading clinical manifestations,

sometimes closely simulating neurotic disorder (Ecker & Kernohan 1941). Later restlessness, excitability and confusion become marked. Severe memory disturbance can occasionally produce the picture of Korsakoff's syndrome. Peripheral neuritis is common, with paraesthesiae, burning pain in the limbs and conspicuous sensory signs. Distal leg weakness may develop with loss of the ankle reflexes.

Thallium

As John Emsley (1978) has remarked, 'If ever an element was cursed at birth, that element was thallium'. Thallium is a rare but highly toxic heavy metal giving rise to significant human exposure from environmental, industrial and (historically) medicinal sources (Peter & Viraraghavan 2005). Thallotoxicosis following acute exposure is marked by gastroenteritis, polyneuropathy and alopecia, whereas that by chronic exposure is marked by anorexia, headache, muscle pain, alopecia, blindness and even death (reviewed by Peter & Viraraghavan 2005). White streaks (Mee's lines) may be seen on fingernails and toenails. Specific treatment is with chelating agents such as Prussian blue (Hoffman 2003). Involvement of the nervous system is a significant feature of thallium poisoning. After small doses ataxia and paraesthesiae develop and may progress to frank peripheral neuropathy. Retrobulbar neuritis is often seen. Tremor, chorea, athetosis and myoclonic jerking are also common. Mental abnormalities (encephalopathia thallica) may be pronounced, with lethargy, impairment of consciousness, memory deficits, paranoia, depression and dementia (Prick 1979). After large doses cerebral involvement is severe, with cranial nerve palsies, delirium, hallucinations, fits and coma. Death often follows from respiratory paralysis.

Follow-up by Reed *et al.* (1963) showed that sequelae were limited to the nervous system, both peripherally and centrally, and occurred in half of the survivors. The enduring deficits consisted of features derived from the acute stage: ataxia, tremor, abnormal motor movements, fits and visual disturbance. A recent neuroimaging study of this rare condition identified abnormalities in the striatum in subjects showing otherwise classical presentation of chronic thallium neurotoxicity (Tsai *et al.* 2006).

Bismuth

Bismuth preparations continue to be used for gastrointestinal and skin disorders as various prescribed and over-the-counter compounds (bismuth subgallate, bismuth subnitrate, tripotassium dicitratobismuthate, bismuth subcitrate and bismuth subsalicylate). Bismuth therapy in gastrointestinal use has shown major efficacy in the treatment of gastroduodenal ulcers. Colloidal bismuth subcitrate is as effective as the histamine H₂-receptor antagonists in peptic

ulcer, with a lower rate of relapse (Caron & Rouveix 1991). Rarely, bismuth is reported as having been used in injection form as a health tonic in developing countries (Addrizzo-Harris *et al.* 1997). Chronic uncontrolled use of bismuth salts is associated with a range of toxic symptoms. Most patients affected have been between 40 and 80 years old, with more women than men affected.

Collignon *et al.* (1979) analysed reports of 99 cases in the literature and describe seven patients of their own. Neurological abnormalities are prominent during the prodromal phase, with disturbances of gait and balance, tremors, myoclonic jerks and other disorders of movement. Headache, insomnia and apathy may be accompanied by difficulties with thinking and memory. Some patients show marked oscillations between depression and euphoria. Buge *et al.* (1981) report occasional patients with visual hallucinations and persecutory delusions. Such prodromata can last for several weeks or months.

The acute encephalopathy then presents with confusion and clouding of consciousness, often accompanied by considerable excitement and agitation. Disturbances of memory and praxis sometimes dominate the picture and myoclonic jerks are almost universal. Up to one-third of patients suffer generalised seizures. Motor neurological abnormalities are marked while blood bismuth levels are high. Von Bose and Zaudig (1991) report a more recent example in which rapidly progressive dementia, intermittent delirium, ataxia and myoclonus led to an initial diagnosis of Creutzfeldt-Jakob disease.

As the acute organic reaction subsides the patient may recover completely, or be left with short-term memory difficulties or more global defects of intellectual function. These can persist for more than a year in certain cases. Collignon *et al.* (1979) stress apraxic and agnosic deficits that may remain along with the memory disorder. The picture may mimic the presenile or senile dementias (Summers 1998) or chronic subdural haematoma, or may suggest the presence of a frontal lobe lesion.

Buge *et al.* (1981) have described characteristic CT appearances during the acute phase, with hyperdensities in the cerebral cortex, cerebellum and basal ganglia due to the presence of bismuth. These disappear slowly over 2–3 months on recovery, although enlargement of the cortical sulci may sometimes persist. A characteristic EEG pattern in patients with encephalopathy has been found to consist of monomorphic waves of 3–5 Hz involving tempororolandic and frontal areas, often spreading occipitally. A diffuse beta rhythm of low voltage is also seen but no spikes or other paroxysmal features. The EEG changes appear consistent even in different patients with markedly different blood bismuth levels, ranging from 150 to 1600 µg/L (normal level is ≤5 µg/L). Blood bismuth levels, however, may not accord with actual brain tissue concentrations (Supino-Viterbo *et al.* 1977).

Organophosphorus compounds

Complex esters of phosphoric acid and its derivatives are widely used in industry, horticulture and agriculture. Prominent among them are pesticides such as parathion and malathion, also diazinon and chlorfenvinphos used in sheep dip. Chemical warfare agents include sarin, tabun and soman. Such compounds are potent inhibitors of acetylcholinesterase, first binding to phosphorylation sites, then altering membrane function in a manner that can lead to delayed neurotoxicity. They also interact with adrenergic, dopaminergic and serotonergic mechanisms (Bradwell 1994).

Acute toxic effects consist of cholinergic crises with miosis, bronchoconstriction, diarrhoea, bradycardia and cardiac dysrhythmias. Many patients show weakness due to depolarisation block of neurotransmission, with areflexia and fasciculations (Donaghy 1993). Tremors, ataxia, confusion and agitation may develop, sometimes with bulbar signs and convulsions. Respiratory failure is the usual mode of death. In less severe cases a progressive sensorimotor polyneuropathy follows the acute symptoms after a delay of 1 or 2 weeks. Severe quadriparesis may result. Cognitive deficits have been identified in several epidemiological studies, often persisting for several years after acute exposure (Steenland 1996).

Less intense and intermittent exposure may lead to chronic complaints of nausea, headache, cramps and dizziness, sometimes with muscle fasciculations and difficulty in focusing the eyes. Tiredness and hypersomnia are prominent. Hartman (1988) and Steenland (1996) review neuropsychological studies that have shown impairments of sustained attention and information processing. Florid psychiatric pictures resulting from chronic exposure have been described by Gershon and Shaw (1961) in 16 patients. Most were farmers or greenhouse workers who had used pesticide sprays without adequate protection. After some years of exposure seven developed depressive illnesses, five schizophrenic reactions and four presented with cognitive difficulties. Most had had episodes of acute poisoning in the past with classic symptoms and signs. Bradwell (1994) has reported a farm worker chronically exposed to weedkillers and pesticides who suffered repeated episodes of acute organic psychosis, also periods of depression and mania over several years, all against a background of chronic anergia and hypersomnia. Recent reviews include Rusyniak and Nanagas (2004), Wesseling and Keifer (2002) and Levin and Rodritzky (1976).

Methyl bromide

Methyl bromide is a monohalogenated methane. It exists as a colourless odourless gas and is naturally produced in oceans. It can be pressurised to a liquid and has sometimes been used

as a fire extinguisher and refrigerant but more commonly as a fumigant and insecticide.

Over 300 cases of systemic methyl bromide poisoning have been reported, with around 60 fatalities (Herzstein & Cullen 1990; Deschamps & Turpin 1996). Toxic exposures in humans have been documented from inhalation (Deschamps & Turpin 1996), dermal abrasions (Lifshitz *et al.* 2000) and contact with contaminated plastic sheeting (Herzstein & Cullen 1990) and leaking old fire extinguishers (Hoizey *et al.* 2002).

Severe exposures are fatal, with acute pulmonary oedema, renal failure and convulsions (De Jong 1944). Brief exposures are followed by headache, nausea and vertigo, then a characteristic interval of hours or even days during which the patient is symptom-free. This may be followed by the explosive onset of headache, muscular twitching, convulsions, delirium, visual disturbances and somnolence progressing to coma (Baker & Tichy 1953). Chronic mild exposure may be followed by peripheral neuropathy. Fumigation workers with chronic mild exposure were found to show significantly reduced performance on tests of cognition, manual dexterity and olfaction (Calvert *et al.* 1998).

Indirect measures of exposure are provided by serum bromide levels (Buchwald 2001) as the parent agent is rapidly reduced. Methyl bromide shows both enzymatic and non-enzymatic conjugation with glutathione (via the enzyme erythrocyte glutathione transferase). Methyl bromide is metabolised by glutathione conjugation and excreted as carbon dioxide. Methyl bromide causes carcinoma in animal exposures, but data about its carcinogenicity in humans is lacking (Anon. 1999).

Carbon disulphide

Carbon disulphide is an organic solvent. It is a constituent of lacquers and varnishes, and is used in industry in the manufacture of rubber and plastics, notably rayon. Disorders of the CNS are more common the heavier the exposure to carbon disulphide (Krstev *et al.* 2003).

The commonest toxic effect is peripheral neuritis affecting both motor and sensory nerves and producing aching cramp-like pains in the limbs. Visual changes also occur, with central scotomata and concentric narrowing of the visual fields. Auditory symptoms include tinnitus and deafness, and dizziness may occur. Mental changes may be profound and can be the presenting feature. A variety of subjective symptoms are described (Takebayashi *et al.* 1998). These include a heavy feeling in the head, light-headedness, fainting after suddenly standing up, tremor, dullness, and increased sensitivity of the skin in the extremities. An effect on glucose metabolism, with some heavily exposed workers showing increased concentrations of glycosylated haemoglobin, has also been described. Both insidious changes of personality and acute toxic psychoses have been described (Braceland 1942).

Personality changes consist of mood swings, irritability and outbursts of inexplicable rage. The worker may be exhilarated when breathing the fumes in the factory but depressed when at home. Constant fatigue may progress to a state of profound apathy. Headache, anorexia and insomnia are usually marked, and loss of libido is common. Later there may be difficulties with memory, and auditory and visual hallucinations may occur.

In Braceland's survey the more acute psychoses were usually sudden in onset and sometimes closely resembled episodes of mania. These appear to be uncommon today now that levels of exposure in the workplace have been regulated. Severe confusion was accompanied by noisy aggressive behaviour, delusions and hallucinations. Most cleared rapidly on admission to hospital, but some could last for many weeks or months. Residual memory defects occasionally persisted. Examples of acute schizophrenia-like psychoses were also reported, probably in those who were specially predisposed.

Hartman (1988) reviews the cognitive effects of chronic exposure. Motor speed, reaction time, vigilance and visuo-constructive abilities have proved to be affected, sometimes showing significant correlations with duration of exposure. In Huang's study of 10 workers (1996) in a viscose rayon plant subjected to long-term exposure, who had polyneuropathy and various neuropsychiatric symptoms, EEGs were all normal. Brain CT showed mild cortical atrophy in three workers, and low-density basal ganglia lesions in three others. Brain MRI showed multiple lesions in the basal ganglia and corona radiata, but not in all cases. Carotid duplex sonography revealed mild atherosclerosis with plaques in extracranial vessels in over half.

Carbon disulphide neuropathy may persist for a long time. On MRI, multiple high signal intensities in the basal ganglia and subcortical white matter suggest a vascular process, particularly in the small vessels. Diffuse demyelination in the cerebral hemispheres and diffuse decrease in regional cerebral blood flow suggest a microangiopathic process. Carbon disulphide exposure is a risk factor for stroke and a cause of diffuse leucoencephalopathy. Carbon disulphide may induce parkinsonian features and therefore needs to be differentiated from idiopathic parkinsonism (Huang 2004).

Movement Disorders

Max Henderson¹ and John D.C. Mellers²

¹Institute of Psychiatry, King's College, London

²Maudsley Hospital, London

The movement disorders form a substantial part of neurological practice and have gradually attracted increasing psychiatric interest. This is partly on account of their psychiatric concomitants, for example a high incidence of depression in Parkinson's disease and of behavioural disturbance in the opening stages of hepatolenticular degeneration. Biochemical research, particularly in relation to dopamine metabolism, has revealed analogies between the changes thought to underlie certain movement disorders and those postulated to occur in major psychiatric illnesses. Yet more striking has been the explosion in the use of functional neuroimaging techniques, which have produced a more detailed understanding of both normal and abnormal cerebral activity. An increased awareness of biological substrates for aspects of neurological conditions previously thought to be 'functional' has followed. Ultimately these developments promise new treatment options.

Traditional neuroleptic medications induced a wide range of movement disorders. Both neurologists and psychiatrists were required to be conversant in their management. Whilst this undoubtedly remains the case, the growth in the use of the atypical antipsychotics has resulted in a fall in the incidence of drug-induced motor symptoms. Prescribers now need to be aware of other complications such as obesity and diabetes.

Other movement disorders, such as spasmodic torticollis, blepharospasm and Gilles de la Tourette's syndrome, reflect the striking influence that mental factors may bring to bear on motor dysfunction. So close is this interaction that psychogenic factors may appear to be solely responsible for causing such conditions, yet other evidence suggests that cerebral malfunction may be primarily to blame. Marked psychosensitivity need carry no implications for psychogenesis *per se*, yet attempts to discern the true situation can prove to be difficult. In the discussion of such disorders below, the arguments advanced in both directions will be presented.

Drug-induced disorders

Soon after the introduction of phenothiazines to psychiatric practice it became apparent that extrapyramidal movement disorders ranked high among the unwanted effects of treatment. Until the introduction of clozapine, the successive development of new neuroleptics failed to solve the problem, in that all major tranquillisers appeared to share these side effects in some degree. Indeed, their propensity to disturb extrapyramidal function proved to be roughly proportional to their antipsychotic effect, although earlier ideas that the two were necessarily linked to one another have not been upheld.

Among the phenothiazines, those with a piperazine side chain (e.g. trifluoperazine) show more marked extrapyramidal effects than those with aliphatic or piperidine side chains (e.g. chlorpromazine, thioridazine). The butyrophenones (haloperidol, benperidol, droperidol) are particularly potent in this regard. The thioxanthenes (e.g. flupentixol) may induce the whole range of disorders considered below. The atypical antipsychotics show a much reduced propensity to produce movement disorders but the risk is not eliminated.

Clinical pictures

Four main syndromes have been delineated, namely parkinsonism, akathisia, acute dystonic reactions and the group of disorders at present subsumed under the term 'tardive dyskinesia'. Tardive dystonia and tardive akathisia have been recognised more recently. Precise estimates of the incidence of all such conditions have been hard to obtain, on account of variations in prescribing practice and differences in the populations surveyed. Nevertheless, it is now firmly established that the drugs are to be blamed rather than inherent aspects of the psychiatric disorders themselves. Exactly analogous movement disorders are induced whether

the neuroleptics are given for schizophrenia, affective disorder, neurotic disability or for the control of chronic pain. It must be granted, however, that the stereotypies and mannerisms of chronic schizophrenia can at times lead to diagnostic difficulty and even obscure for a while the development of the extrapyramidal symptoms.

The clinical pictures encountered are fully described in comprehensive reviews by Marsden *et al.* (1975), Miyasaki and Lang (1995) and Sachdev (2005) and may be summarised as follows.

Parkinsonism

Parkinsonian features usually develop insidiously, often within a week and almost always within the first month of treatment, often coincident with the onset of antipsychotic activity (Wirshing 2001). The development of parkinsonism is broadly dose dependent, increasing as higher levels of neuroleptics are achieved. However, it emerges in only some 20–40% of persons, individual susceptibility being important. The incidence increases with age, as with idiopathic Parkinson's disease.

All the features of idiopathic Parkinson's disease (see Parkinson's disease and the parkinsonian syndrome, later in the chapter) may be induced. Bradykinesia is the earliest and commonest sign, with muscular rigidity and disturbance of posture and gait developing later. The upper extremities are commonly affected first followed by the jaw and then the lower extremities. The symptoms are usually bilateral (Sachdev 2005) and are more commonly symmetrical than in idiopathic Parkinson's disease (Rodnitzky 2002). Tremor is a good deal less common than with the idiopathic disease, the exception being the occasional appearance late in the course of treatment of fine perioral tremor ('rabbit' syndrome). The latter generally sets in after months or years of therapy as with tardive dyskinesia. Sialorrhoea may occur due to a reduced swallowing rate, in contrast to that associated with clozapine which is caused by increased saliva production (Wirshing 2001).

With continuation of the drugs the parkinsonian features may gradually subside as tolerance develops. Short of this they will usually resolve over the course of several weeks when the drugs are stopped. However, Marsden and Jenner (1980) stress that occasional patients continue to show parkinsonism for as long as 18 months after cessation of therapy. In the rare examples that fail to recover thereafter, one may usually presume that idiopathic Parkinson's disease had already been present.

With the more severe extrapyramidal reactions provoked by potent neuroleptics, the clinical picture may occasionally come to resemble 'catatonia'. Gelenberg and Mandel (1977) described a group of patients showing negativism, withdrawal, posturing and waxy flexibility, of gradual onset usually in the first few weeks of treatment. Incontinence of urine was sometimes observed. Behrman (1972) has described mutism, sometimes progressing to the full syn-

drome of akinetic mutism. Such developments may easily be confused with worsening of schizophrenic symptomatology, leading to increase in dosage of the offending medication. In contrast, stopping the drugs can lead to slow resolution. The differential diagnosis includes neuroleptic malignant syndrome.

Akathisia

Akathisia consists of motor restlessness accompanied by subjective feelings of inner tension and discomfort referable chiefly to the limbs. It often coexists with parkinsonian features but is possibly even more common: it occurs in up to 90% of young patients but the incidence decrease with age. The symptoms can be considerably distressing and are a frequent cause of poor drug compliance. The patient complains of being driven to move, of pulling sensations in the legs and an inability to keep them still. The disorder usually appears within the first few days of treatment but may only develop as higher dosage is achieved. Both subjective and objective aspects need to be present for the diagnosis and it is now thought that the observable behaviours are a response to these inner feelings of tension (Wirshing 2001). Barnes (1989) has produced a rating scale for assessment of both the observable and subjective components of the syndrome. Sometimes the latter are lacking (pseudokathisia), chiefly in patients with negative psychotic symptoms (Barnes & Braude 1985).

Braude *et al.* (1983) investigated motor restlessness in detail by ratings of subjective sensations and objective manifestations in a large group of patients on antipsychotic medication. A principal components analysis served to delineate the akathisia syndrome more precisely. Mild examples presented mainly subjectively; inner restlessness was a common and non-specific symptom, but complaints clearly referable to the legs characterised the akathisia group. These leg sensations are deep – paraesthesiae are uncommon. Patients with moderate akathisia showed in addition a tendency to rock from foot to foot or to walk on the spot, along with coarse tremor or myoclonic jerks in the feet. Patients with severe akathisia showed difficulty in maintaining their position, for example shuffling or tramping the feet when sitting, rising repeatedly when seated, or walking or pacing when attempting to stand still. In the most severe forms patients may be unable to tolerate any position, whether sitting, lying or standing, for more than a few minutes.

Continuation of the drugs may allow the symptoms to subside, but this is not invariable. An extrapyramidal origin is postulated, but the evidence for this is mainly inferential.

Akathisia must be distinguished from the restless legs syndrome (Ekblom's syndrome) which may resemble it closely (Trenkwalder *et al.* 2005). This is seen in the absence of neuroleptic medication, usually in patients who are otherwise in normal health. However, associations have been noted with iron-deficiency anaemia, renal failure and pregnancy. Physical examination typically shows no neu-

rological abnormality. The condition is more common than previously thought with a prevalence of 6–9% in community surveys. The majority of patients have mild symptoms with spontaneous remissions and never seek medical attention. It may occur at any age, including childhood, but is more common in older people. There is a female preponderance and a strong genetic predisposition.

Diagnostic criteria for restless leg syndrome have recently been defined (Allen *et al.* 2003). An urge to move the legs is usually accompanied by marked leg discomfort, with creeping sensations, dysaesthesiae or sensations of cold or weakness, usually most pronounced in the calves. The desire to move arises directly from such discomforts, which are temporarily relieved by activity such as stretching or walking. Symptoms characteristically show a marked diurnal variation and occur only, or are worse, in the evening and at night. Insomnia and daytime sleepiness are common and may occasionally be severe. In part this is attributable to difficulty getting to sleep because of the symptoms. In addition, however, some 80% of patients have periodic limb movements during sleep: frequent, involuntary, repetitive, stereotyped movements of the legs during sleep that can be associated with microarousals and sleep deprivation. Central dopaminergic abnormalities and disturbances of iron metabolism have been implicated in the disorder. All patients should be investigated for iron deficiency and iron supplements given if serum ferritin is low. Dopaminergic agents are recognised as first-line treatment. Alternatives include opioids, gabapentin and other antiepileptic drugs, clonazepam and clonidine. Long-term treatment with dopaminergic agents may be associated with exacerbation of symptoms, emphasising the importance of treating only significantly disabling symptoms.

Acute dystonia

Acute dystonic reactions are considerably rarer than the above reactions, affecting perhaps some 2% of patients. They develop abruptly and early in the course of treatment, within a few days of oral treatment or within hours of intramuscular injection. The more potent piperazine phenothiazines and the butyrophenones are chiefly responsible. Young adults and children appear to be particularly susceptible, and males have outnumbered females in most surveys. It is more common in those who have previously had a dystonic reaction and in those known to have abused cocaine (Cortese *et al.* 2004; Stubner *et al.* 2004).

The patient is seized with strong sustained or intermittent uncontrolled muscular contractions that are frequently painful and deeply alarming. Deviation of the eyes, blepharospasm, trismus and grimacing are common. Severe examples show tongue protrusion, dysphagia and respiratory stridor. Extension to the neck and trunk can lead to torticollis, retrocollis, writhing and opisthotonos. Continuous slow writhing may affect the limbs, with dystonic postures of hyperpronation and adduction.

Marked examples may be mistaken for status epilepticus or tetanus by the inexperienced observer. Hysteria may be diagnosed when muscular spasms are remittent. The disorder is self-limiting and usually of no more than several hours' duration, although therapeutic intervention will often be indicated for the relief of acute distress.

Tardive dyskinesia

As experience was gained of long-term neuroleptic medication it became apparent that a range of movement disorders make their first appearance only late in the course of treatment. These have attracted considerable attention, on account of their sometimes seriously disabling nature and because in a proportion of patients they can prove to be irreversible. The term 'tardive dyskinesia' is used to refer to such late developments rather than to any phenomenologically distinct dyskinesic picture. Although tardive dystonia and perhaps tardive akathisia are now seen as distinct entities, tardive dyskinesia may include choreiform, myoclonic and athetoid movements.

The commonest site of the abnormal movements is around the mouth and tongue, which become involved in a more or less continuous flow of choreiform activity (orofacial dyskinesia, bucco-linguo-masticatory dyskinesia). The tongue protrudes, twists and curls, along with incessant chewing, pouting and sucking movements of the lips, jaw and cheeks. In severe examples talking and eating can be hampered. The upper face tends typically to be spared, but may show tic-like blinking or blepharospasm. The neck may be affected with twisting dystonic movements.

Involvement of the trunk, arms, hands and legs may also be observed (Kidger *et al.* 1980). The distal extremities show choreiform and athetotic movements, with finger twisting and spreading, tapping of the feet and dorsiflexion of the toes. Abnormalities of gait and posture show as lordosis, rocking and shoulder shrugging. Grunting and disturbance of the respiratory rhythm may be in evidence. Overall, three-quarters of patients have orofacial involvement, half have limb involvement and one-quarter have involvement of the trunk. Factor analysis applied to ratings of involvement of different body regions has suggested that there may be relatively independent subvarieties, affecting respectively the jaws and tongue, the face and lips, and the extremities and trunk (Glazer *et al.* 1988). These may possibly have differing aetiological and prognostic connotations.

Altogether the picture may come to involve a complex admixture of tics, chorea, athetosis, dystonia and myoclonic jerks; however, rhythmic tremor is not seen. It may worsen dramatically with emotional stress and it decreases with drowsiness. Choreiform movements appear to be commoner in the elderly, and dystonic pictures in the young. Age also influences the topography, orolingual movements being especially common in the elderly.

A similar disorder is known to occur spontaneously, especially in the elderly, with up to 6% of those in their seventh decade affected (Klawans 1980). In patients on long-term neuroleptics, however, tardive dyskinesia is far from uncommon. Variable estimates have resulted from different surveys, depending among other factors on readiness to include very minor degrees of movement disorder. The working party appointed by the American Psychiatric Association (Task Force on Late Neurological Effects of

Antipsychotic Drugs 1980) concluded that 10–20% of people given antipsychotic drugs for a year or more could be expected to develop a clinically appreciable tardive dyskinesia, the rate probably being higher in the elderly. A review by Yassa and Jeste (1992) suggested a median figure of 24%. Woerner *et al.* (1998) found a rate of 25% after 1 year's exposure, which increased to 53% after 3 years' exposure. However, disabling degrees are rare. Sachdev (2000) reported that 5–10% of patients will have some degree of functional impairment relating to their tardive dyskinesia. In particular, eating difficulties have led to weight loss. Although cases can follow only 1 month's exposure (Jeste *et al.* 1999), the great majority of patients will have been on neuroleptics for at least 2 years when the disorder makes its first appearance and often for considerably longer. Operational criteria for duration of neuroleptic exposure and chronicity are included in the Diagnostic and Statistical Manual of Mental Disorders (DSM)-IV: 3 months' exposure to neuroleptics is required in the under-60s and 1 month's exposure in the over-60s. The symptoms must last more than 4 weeks. It is labelled 'persistent' if lasting longer than 3 months and 'chronic' if more than 6 months.

Among the predisposing factors highlighted in certain surveys are age, sex and evidence of brain damage. There is a marked increase in incidence after the age of 40, and a female preponderance among the elderly. The influence of pre-existing brain damage has been less uniformly upheld (Sachdev 2005), but associations have been reported with a history of exposure to electroconvulsive therapy (ECT) or leucotomy, likewise evidence of cognitive dysfunction or negative symptoms in schizophrenia (Waddington & Youssef 1986; Barnes 1987). In McClelland *et al.*'s (1991) long-term follow-up of hospitalised patients, the development of facial dyskinesia was significantly associated with ventricular enlargement on computed tomography (CT). More than one study has suggested that patients with a history of acute dyskinesias are at greater risk. Patients with organic psychiatric disorders have shown an especially high prevalence (Yassa *et al.* 1984). An increased risk has been reported in diabetics (Ganzini *et al.* 1991) and van Os *et al.* (1997) reported a threefold increase in risk of tardive dyskinesia in patients who had abused alcohol. A single study has found an association with a variant of the dopamine D₃ receptor gene (Steen *et al.* 1997), and Andreassen *et al.* (1997) reported an increased risk in patients homozygous for mutated alleles of the cytochrome P450 2D6 gene.

The evidence that patients with affective disorders may be more at risk than patients with schizophrenia is reviewed by Barnes (1987), likewise indications that depressive symptomatology in the course of schizophrenia may confer additional risk. There is some evidence that prolonged exposure or exposure to high dosage of neuroleptics may increase the chance of developing the condition, but this is disputed. The Yale study, in which a large cohort of patients was followed

prospectively for evidence of the condition developing, has been exceptional in finding a clear positive relationship to neuroleptic dose (Morganstern & Glazer 1993). It is clear, however, that most patients will have received large total quantities before tardive dyskinesia supervenes. The concomitant administration of anticholinergics appears to increase the severity of the disorder but probably does not alter the risk of its development. Use of atypical antipsychotics carries a significantly lower risk. Jeste *et al.* (1999) reported a 5–10 times lower incidence with risperidone than haloperidol, and Tollefson *et al.* (1997) observed similar results with olanzapine. A noteworthy feature is that the first signs very often make their appearance when the drugs are discontinued or the dosage is lowered. Indeed the previously common practice of 'drug holidays' is associated with an increased risk of tardive dyskinesia (Goldman & Luchins 1984).

A disturbing aspect of the condition is its liability to persist despite stopping the medication. A majority of patients will improve substantially, usually within months but sometimes taking 1 or 2 years for complete resolution. Between one-quarter and half of all patients may be expected to improve markedly within a year (Task Force on Late Neurological Effects of Antipsychotic Drugs 1980). More recent 5-year follow-up data from Bergen *et al.* (1989) showed about half were stable and unchanging, one-quarter showed a fluctuating course, 11% improved and 8% worsened. Between years 5 and 10, half of patients will show a reduction in symptoms of 50%. In children complete recovery can be predicted, but in some 30% of adults the condition seems destined to be permanent, especially in the elderly.

In addition to neuroleptics, the condition may follow the prescription of other medications that also affect dopamine neurotransmission. Examples include oral contraceptives, anticonvulsants, tricyclic antidepressants and dopaminergic drugs which are not antipsychotics such as metoclopramide (Leo 1996). Similar dyskinesias are seen in frank neurological disorders such as Huntington's disease, Sydenham's chorea, Hallervorden-Spatz syndrome and Fahr's disease.

Tardive dystonia

Burke *et al.* (1982) and more recently Rodnitzky (2002) have described a syndrome of 'tardive dystonia' that appears to be attributable to antipsychotic medication. As with tardive dyskinesia it typically follows several years of treatment with the drugs, and once established tends to be persistent. However, the nature of the movement disorder is quite different. The dystonia consists of sustained slow twisting movements affecting the limbs, trunk, neck or face. Unlike tardive dyskinesia, it typically causes severe distress to the patient and can result in significant neurological disability.

The disorder typically begins after 3–7 years of neuroleptic exposure but may occur within the first year (Burke *et al.*

1982; Kang *et al.* 1986, 1988). Males may be affected earlier than females (Kiriakakis *et al.* 1998). Onset in some two-thirds of patients is focal. As the dystonia progresses there is usually spread so that by the time the condition plateaus, usually after several months, over two-thirds of cases have a segmental dystonia, with some 15% having a generalised distribution. Younger patients tend to have a more generalised picture, older patients more focal. Focal cases may present identical pictures to torticollis, blepharospasm or oromandibular dystonia. The presentation in generalised cases may be indistinguishable from idiopathic torsion dystonia, though a family history of such a condition is lacking. Sustained postures are sometimes seen in addition to the slow twisting movements, sometimes relieved by small tactile manoeuvres as in dystonia generally (see under The dystonias, later in chapter). The movements generally abate during sleep. A history of tardive dyskinesia is seen in approximately half of patients, although pharmacologically the two disorders are distinct: anticholinergic agents are sometimes beneficial for the dystonic movements but tend to exacerbate tardive dyskinesia. Withdrawal of neuroleptics is the mainstay of treatment but prognosis is disappointing. Up to half of patients will show some improvement but remission is seen in less than 15%. Exposure to neuroleptics for less than 10 years predicted a favourable outcome in one study (Kiriakakis *et al.* 1998).

Davis *et al.* (1988) extended the spectrum of disorders encountered, reporting three patients with laryngospasm as part of the clinical picture, sometimes developing abruptly and requiring tracheostomy, and two patients with spasmodic dysphonia.

In all cases differentiation must be made from Wilson's disease by appropriate diagnostic studies, also from other symptomatic dystonias when there are abnormal neurological signs. A primary blepharospasm, oromandibular dystonia or torticollis must be considered when there are no dyskinesic movements. The distinction from classic tardive dyskinesia can at times be difficult and both may occur together; the distinction is chiefly important because of the different options presented for treatment (see Management/Tardive dystonia, later in chapter). Finally, it is important to beware of mistaking the picture for a psychogenic disorder, particularly when the movements are bizarre or influenced transiently by emotion, suggestion or an interview after amobarbital administration.

Tardive akathisia

A syndrome of 'tardive' or 'chronic' akathisia has been distinguished from the acute form, usually developing after some years on neuroleptics. It may coexist with features of tardive dyskinesia, including orofacial dyskinesia and choreoathetoid movements of the limbs, and like tardive dyskinesia it may worsen on dose reduction whereas acute akathisia tends to be aggravated by increase in dosage.

Burke *et al.* (1989) have presented the features seen in 52 cases. The condition had developed after a mean of 4.5 years on dopamine antagonists, but in one-third had developed within a year. Complex stereotyped movements consisted of marching on the spot, frequent crossing and uncrossing of the legs, trunk rocking, grunting, moaning and face rubbing or scratching. Half of the patients managed to stop neuroleptics, and the symptoms then persisted for a mean of 2.5 years. The younger patients did better than the old. Attempts at therapy were frequently disappointing (see Management/Tardive akathisia). The condition can be profoundly disabling, leading to inner torment, irritability and inability to concentrate.

Pathophysiology

The pathophysiology of the neuroleptic-induced movement disorders appears to be associated with various aspects of the dopamine–acetylcholine balance within the brain, more particularly within the corpus striatum. However, earlier views have become progressively more complex, with the discovery of both inhibitory and excitatory dopamine receptors in the striatum, and the demonstration of feedback striatonigral pathways that may be mediated in part by cholinergic or γ -aminobutyric acid (GABA)ergic mechanisms. The maintenance of correct dopamine and acetylcholine levels in the striatum is clearly under highly complex control and stands to be disturbed in a multitude of ways. Hence, no doubt, the variety of movement disorders encountered when this balance is altered by drugs. Discussions of the hypotheses put forward in attempts at explanation are provided by Marsden and Jenner (1980), Baldessarini and Tarsy (1980), Miyasaki and Lang (1995) and Casey (2004).

Among their many pharmacological actions, all neuroleptics have powerful effects on cerebral dopamine mechanisms. These correlate highly with their antipsychotic potency. The phenothiazines, butyrophenones and thioxanthenes act specifically to block cerebral dopamine D_2 receptors. Reserpine and tetrabenazine operate differently, interfering with the intraneuronal granular uptake and storage of dopamine. Clozapine differs from the typical antipsychotics in that it has weak effects on striatal dopamine D_2 receptors, high affinity for D_4 and D_1 receptors, and a relatively strong blocking effect on serotonin S_2 receptors (Advokat 2005).

Drug-induced parkinsonism appears to be chemically closely analogous to naturally occurring Parkinson's disease. The blockade of dopamine receptors within the striatum amounts to 'chemical denervation', resulting in relative dopamine deficiency. Anticholinergic drugs can accordingly be of benefit by helping to restore the correct dopamine–acetylcholine balance. More complex theories are now emerging that relate to the speed with which the

drug dissociates from the dopamine receptor (Kapur & Seeman 2001). The rapid dissociation hypothesis suggests that atypical antipsychotics bind to D₂ receptors for long enough to be antipsychotic but not long enough to cause parkinsonism.

The genesis of akathisia is little understood, but may rest on dopamine receptor blockade in brain areas other than the striatum. It is interesting that this is the only form of movement disorder which may develop within a few hours of starting treatment, i.e. within the time frame of dopamine receptor blockade with neuroleptics. However, it is clear from pharmacological responses that other neurotransmitters must also be involved, including central adrenergic systems. Separate pathophysiology is thought to be involved in the acute and tardive forms given that acute forms worsen with an increase in neuroleptic dose whereas the tardive form improves.

The mechanisms underlying acute dystonic reactions also remain obscure. Their peak incidence at 24–48 hours from the initiation of therapy is well after the peak onset of dopamine receptor blockade. They may reflect interference with presynaptic dopamine mechanisms, or there may be a mismatch between excess release of dopamine and coincident hypersensitivity of dopamine receptors. Neuroleptics principally occupy D₂ receptors, and the increased dopamine turnover may be expressed through overactivation of unblocked D₁ receptors. Again, however, it is likely that other neurotransmitter systems are also implicated; Jean-jean *et al.* (1997) suggest neuroleptic binding to σ opiate receptors is important.

There is probably not a unitary pathophysiology for tardive dyskinesia; various patterns of movement emerge after varying lengths of treatment and differ in their persistence. It has been especially difficult to explain why drugs which block striatal dopamine receptors should eventually produce forms of dyskinesia known to be associated with dopamine overactivity in the striatum. Thus the choreiform movements of tardive dyskinesia resemble those seen as a complication of levodopa therapy in Parkinson's disease, and the administration of levodopa or anticholinergic drugs exacerbates the condition. The prolonged blockade may have led to this end-result by virtue of increased dopamine turnover coupled with upregulation of receptor numbers, possibly with an imbalance between D₁ and D₂ receptors. Alternatively, hypersensitivity of D₂ receptors may cause them to respond abnormally to the dopamine reaching them (Klawans *et al.* 1980). Hypersensitivity of this nature probably accounts for the worsening of the condition on withdrawal of neuroleptics and the success of their reintroduction in ameliorating the condition. However, attempts to demonstrate dopamine receptor supersensitivity by positron emission tomography (PET) or at autopsy have been relatively unsuccessful.

Animal studies have indicated that over the course of prolonged neuroleptic administration, dopamine receptor

blockade may actually slowly disappear, giving way to supersensitivity in its place. Moreover, the latter can be shown to persist for many months after withdrawal, providing an analogy to the possible situation in tardive dyskinesia in humans (Clow *et al.* 1979a,b). It remains difficult, nevertheless, to reconcile the very late appearance of tardive dyskinesia with the supersensitivity known to develop soon after starting neuroleptics, and it is likely that complex interactions with other neurotransmitters are also partly responsible. A role for GABA neurones in the striatum has been suggested (Gerlach & Casey 1988).

No convincing pathology has been described in the brain to account for those tardive dyskinesias that become irreversible. Structural or neurotoxic changes in the neurones, affecting their membranes or the cell respiratory mechanisms, must nevertheless be postulated in such cases. One such theory is suggested by Cadet and Lohr (1989) and Gunne and Andren (1993), who argue that tardive dyskinesia results from neuronal loss especially of GABAergic neurones projecting from the globus pallidus to the thalamus. This may be due to excess free radicals or excitotoxicity, both of which lead to apoptotic cell death. This cell death leads to disinhibition of lateral pallidal neurones, which may be responsible for the hyperkinetic state of tardive dyskinesia. A number of lines of evidence support this hypothesis. Neuroleptics increase catecholamine turnover, which leads to excess free radical production. They also lead to accumulation of iron in the basal ganglia. Some (mixed) reports find a beneficial role for antioxidants in the treatment and prevention of tardive dyskinesia. Finally, it is consistent with age, diabetes, smoking and brain damage being additional risk factors (Sachdev 2000).

Management

The management of movement disorders occurring as side effects of antipsychotic treatment must take into account every effort at prevention. As we have seen, the range of movement disorders encountered is, at the very least, stigmatising and at worst profoundly disabling and tormenting. Most physicians are now reluctant to prescribe neuroleptics as first-line drugs and will instead opt for atypical antipsychotics. If a conventional neuroleptic is to be prescribed, there is no firm evidence that any particular phenothiazine, butyrophenone or thioxanthene is less hazardous than others. Dosage and duration of neuroleptics should be kept to a minimum and long-term maintenance therapy strictly reserved for patients in whom definite benefit can be expected. In practice this usually means patients with chronic schizophrenia of a type liable to manifest ongoing positive symptoms in the absence of medication. Where a movement disorder has developed, clearly drug withdrawal is the first step. In cases where antipsychotic treatment is still required there is obviously an even

more compelling argument in favour of switching to an atypical agent.

Parkinsonism

Anticholinergic drugs are of value in controlling drug-induced parkinsonism. It often transpires, however, that once parkinsonian features have come under control, the antiparkinsonian medication can be withdrawn without recrudescence of the motor disorder. It should therefore be tapered off after 3 months for a trial period. Long-continued anticholinergic administration as a routine adjunct to neuroleptic treatment is now considered to be contraindicated. Levodopa should theoretically help drug-induced parkinsonism, but has been little used to date. Some reviewers suggest it is ineffective (Sachdev 2005).

Akathisia

When akathisia is a persisting and disabling complaint the most decisive remedy is reduction of drug dosage (Braude *et al.* 1983). Benzodiazepines may help in some degree as may amantadine or clonidine (Miller & Fleischhacker 2000). Anticholinergics are now rarely used because of a lack of effectiveness and because of the risk of exacerbating tardive dyskinesia. However, the most encouraging results appear to be obtained with beta-blockers such as propranolol, which can reduce both subjective and objective manifestations of the syndrome (Adler *et al.* 1986) possibly by having some cross-affinity with serotonergic receptors.

Acute dystonia

For acute dystonic reactions, anticholinergic drugs are best given parenterally. Benztropine, diphenhydramine and procyclidine can be administered intravenously and are often dramatically effective. Intravenous diazepam can also help. For milder reactions it is important to remember the efficacy of non-specific calming of the patient, or simple sedation with diazepam. The previous occurrence of dystonic reactions constitutes one of the few indications for the prophylactic prescription of anticholinergic drugs from the start of a course of neuroleptic medication, although care needs to be taken with elderly patients.

Tardive dyskinesia

Once tardive dyskinesia is detected, anticholinergic drugs should be discontinued immediately. The next step is to reduce the dosage of neuroleptics gradually and if possible stop them altogether. This may lead to an initial worsening of the condition, but in favourable cases it will be a temporary exacerbation. Some 30–50% of patients will improve as a result, but this may occur only gradually over a number of months or years. If the mental state does not permit total withdrawal, it may be possible to settle for a lower dose. Current practice often consists of substituting the current medication with another (Taylor *et al.* 2005). Some evidence suggests that clozapine may be an effective treatment for tardive dyskinesia (Casey 1989; Louza & Bassitt 2005). When

the movements persist, other treatments may be tried but the number advocated indicates that none is universally successful. Drugs that deplete striatal dopamine may be used (Teoh 1988). Tetrabenazine is the only licensed treatment in the UK but should be avoided in patients with pre-existing depression. Donepezil has shown benefits in a single study (Caroff *et al.* 2001). Benzodiazepines may be useful by virtue of their sedating effect and are widely used. More recent treatments evaluated by double-blind comparisons include clonazepam (Thaker *et al.* 1990) and vitamin E used as a free-radical scavenging agent (Elkashef *et al.* 1990). Gabapentin appears to be effective, adding weight to the theory that GABAergic mechanisms improve tardive dyskinesia (Hardoy *et al.* 1999). Evidence is also available for melatonin (Shamir *et al.* 2001) and pyridoxine (Lerner *et al.* 2001).

Quite often, however, it will be found that no available therapy ameliorates the condition and one must merely hope for spontaneous resolution. The temptation to control the dyskinesia by reintroducing neuroleptics at increased dosage is strictly to be avoided, except in those rare cases where life is threatened by the severity of the involuntary movements. While it may be highly efficacious in producing short-term relief, this merely postpones the problem by reinstating the original pathogenesis and can be expected to worsen the ultimate disability.

Tardive dystonia

Tardive dystonia presents equally severe management problems and the results of treatment are often disappointing. The first step should be to taper or discontinue the causative drugs or change to alternative therapy. Anticholinergic drugs such as trihexyphenidyl (benzhexol) can help, though at the expense of worsening any coincident tardive dyskinesia. Reserpine or tetrabenazine were associated with improvement in two-thirds of patients (Kang *et al.* 1986). Diazepam, lorazepam or baclofen may also be successful.

Clozapine holds special promise and has been reported to help after fruitless attempts with other drugs, leading to slow improvement over several months (Lamberti & Bellnier 1993). It would certainly appear to be the drug of choice in patients whose psychosis requires the continuation of neuroleptics (Friedman 1994; Van Harten *et al.* 1996; Karp *et al.* 1999). The combination of clozapine and clonazepam has sometimes proved to be particularly effective (Shapleske *et al.* 1996). If the dystonia is localised, for example in the cervical region, botulinum toxin might be used (Brashear *et al.* 1998; Molho *et al.* 1998). There is a single report of bilateral thalamotomy being effective (Yadalam 1990).

Tardive akathisia

Treatment of tardive akathisia can be particularly difficult, not least because discontinuation of neuroleptics may lead to transient worsening. This should nevertheless be attempted, even though few cases will benefit substantially. Burke *et al.* (1989) found that reserpine and tetrabenazine

were the most successful drugs, though only one-third of their patients achieved complete resolution of symptoms. Anticholinergics and beta-blockers were without effect, although lorazepam improved occasional patients markedly. Sometimes the reintroduction of neuroleptics at higher dosage may ultimately need to be tried.

Parkinson's disease and the parkinsonian syndrome

The cardinal neurological deficits that comprise the syndrome of parkinsonism are tremor, muscular rigidity, bradykinesia and postural abnormality. A large number of other associated features are also characteristic as described below.

By far the commonest form is idiopathic parkinsonism or paralysis agitans, as described by James Parkinson in 1817. This owes its origin to a specific degeneration of pigmented cells in the brainstem, particularly those of the substantia

nigra. Substantial changes in our understanding of the genetic aspects of the disease have occurred in the last decade. The background lifetime risk of 2% (Elbaz *et al.* 2002) doubles where there is a positive family history (Fahn 2003) and a genetic component is more likely in those whose symptoms start before the age of 50 (Tanner *et al.* 1999).

Since 1997 at least 11 genes or genetic loci have been associated with Parkinson's disease (Dekker *et al.* 2003; Pankratz & Foroud 2004; Hague *et al.* 2005). At present these genes account for only a very small proportion of patients with the disorder and yet these discoveries have led to a better understanding of the pathogenesis of Parkinson's disease and promising directions for developing entirely new approaches to treatment. The genes and loci have been designated *PARK-1*, *PARK-2*, etc., corresponding approximately to the order in which they were discovered (Table 12.1). In most cases the genes and loci have been identified in very rare families showing a simple mendelian pattern of disease inheritance, but some of these findings are now being

Table 12.1 Genes and loci associated with Parkinson's disease. (Adapted from Dekker *et al.* 2003 and Hague *et al.* 2005.)

Locus	Gene	Chromosomal location	Inheritance	Onset	Clinical features	Estimated attributable risk
<i>PARK-1</i>	α -Synuclein	4q21–q23	AD	Late	Less tremor, rapid progression	Small
<i>PARK-2</i>	Parkin	6q25.2–q27	AR	Early: juvenile	Dyskinesia, dystonia Slow progression	PD overall: 0.4–0.7% Early onset PD: 9–18% Early-onset recessive PD: 49%
<i>PARK-3</i>		2p13	AD	Late	Dementia in some patients	Small
<i>PARK-4</i>	α -Synuclein triplication	4q21–q23	AD	Early	Rapid progression, postural tremor, late dementia	Single report
<i>PARK-5</i>	<i>UCHL-1</i>	4p14	AD	Late	None	Single report
<i>PARK-6</i>	<i>PINK-1</i>	1p35–p36	AR	Early	Slow progression	Early-onset recessive PD: up to 15%
<i>PARK-7</i>	<i>DJ-1</i>	1p36	AR	Early	Slow progression	Locally in Dutch isolate: 33% early-onset PD Generally: unknown
<i>PARK-8</i>	<i>LRRK-2</i>	12p11.2–q13.1	AD	Late	None	1–6% prevalence in familial and sporadic PD
<i>PARK-9</i>		1p36	AR	Juvenile	Kufor–Rakeb syndrome, spasticity, dementia, supranuclear gaze paralysis	Single report
<i>PARK-10</i>		1p32	NM	Late	None	Linkage to age at onset reported in Icelandic study
<i>PARK-11</i>		2q36–q37		Late	None	

AD, autosomal dominant; AR, autosomal recessive; LRRK-2, leucine-rich repeat kinase 2; NM, non-mendelian; PD, Parkinson's disease; UCHL-1, ubiquitin carboxy-terminal hydrolase 1.

extended in order to identify putative genetic vulnerability factors in apparently sporadic (idiopathic) Parkinson's disease. The first gene to be identified was α -synuclein on chromosome 4. Three autosomal dominantly inherited point mutations in this gene have been described, including the original Greek family, other southern Mediterranean families and a single German family. A family with triplication of a large region that included the α -synuclein gene has also been reported. In contrast, many different mutations have been described in the parkin gene on chromosome 6. Parkin mutations may account for up to 50% of early-onset cases showing an autosomal recessive pattern of inheritance, but have also been described in patients with late-onset apparently sporadic Parkinson's disease and have been reported as showing autosomal dominant inheritance. Leucine-rich repeat kinase 2 has been identified as the causative gene at the *PARK-8* locus for an autosomal dominantly inherited disease. More significantly, a mutation in this gene has now been described in up to 6% of patients with apparent sporadic Parkinson's disease.

While the α -synuclein gene has been identified in only a few families, its discovery has been of great importance because it has provided new insights into the pathogenesis of Parkinson's disease. The identification of α -synuclein in particular, but also that of parkin and some of the other genes, have disclosed an important pathogenic role for the ubiquitin-proteasome system, a cytoplasmic complex that breaks down aggregates of misfolded, unassembled or damaged protein. Aggregates of α -synuclein are a substrate for breakdown by the ubiquitin-proteasome system. Mutant α -synuclein protein is associated with excess aggregate formation, as are a variety of environmental factors including oxidative stress, heavy metals and pesticides. Although such aggregation may represent a protective mechanism, it appears that when aggregate formation exceeds the capacity of the proteasome system, it accumulates (as Levy bodies) and is associated with cell death (apoptosis). Genetic mutations in parkin and ubiquitin carboxy-terminal hydrolase 1 (in *PARK-5*) lead to impaired protein degradation by the proteasome. Novel therapeutic possibilities include neuroprotective strategies targeting proteins in the proteasome system, aiming to inhibit aggregate formation or enhance protein degradation. There has been considerable interest in the possibility of genetic testing but because the genes identified so far are relatively rare and in many cases of uncertain penetrance, there is no agreed protocol for genetic testing or counselling. However, the field is developing rapidly.

A parkinsonian picture may be induced by certain medications such as reserpine, phenothiazines, butyrophenones and methyldopa (drug-induced parkinsonism). This tends to remit slowly over several weeks or months when the offending drug is withdrawn. A similar syndrome, postencephalitic parkinsonism, was a common aftermath of the pandemics of encephalitis lethargica that occurred almost

80 years ago (see Course and outcome, later). Cases could appear up to 20 years after the original infection, which was sometimes very mild. An early age of onset suggested the postencephalitic variety, also oculogyric crises, abnormal pupil reactions or continuing marked sleep disturbance.

Many other conditions that affect the basal ganglia may cause akinetic rigid syndromes along with other features resulting from diffuse brain damage, for example repeated head injuries in boxing, cerebral syphilis, anoxia due to cardiac arrest, or poisoning with carbon monoxide or manganese. Such a syndrome may appear as part of other degenerative disorders, such as progressive supranuclear palsy, multiple system atrophy, Alzheimer's disease, Lewy body dementia, Wilson's disease or cerebral arteriosclerosis. The latter, however, is no longer recognised as a cause of Parkinson's disease *per se*, and the category of 'arteriosclerotic parkinsonism' has fallen into disrepute (Eadie & Sutherland 1964; Pallis 1971). Certainly the clinical features that were used to delineate this form of the syndrome were variable from one observer to another. An arteriosclerotic origin tended to be blamed when the onset had been acute or progression had occurred in a step-like manner, when progressive dementia coincided with or preceded the parkinsonism, or when pseudobulbar palsy or pyramidal deficits were present. *Marche à petit pas* seemed also to be characteristic of the variety. However, it is hard to establish a causal relationship to cerebral arterial disease when this exists, and the two disorders may simply occur together by coincidence. In Eadie and Sutherland's (1964) study no more clinical evidence of arterial disease could be found in a large group of parkinsonian patients than among equivalent age-matched controls. Nonetheless, the area remains of interest to a number of investigators. Improvements in clinical diagnosis mean that only 1% of the UK Parkinson's Disease Brain Bank series needed reclassifying to vascular parkinsonism. It has been estimated to account for only 3% of cases of parkinsonism in elderly Europeans (de Rijk *et al.* 1997). Winikates and Jankovic (1999) have devised a rating scale for the diagnosis of vascular parkinsonism.

Clinical features

The idiopathic disease is slightly commoner among men than women. The mean age of onset is 55 years with two-thirds of cases beginning between 50 and 59 (Hoehn & Yahr 1967). Excellent accounts of the clinical features and natural history are given by Selby (1990), Pearce (1992) and Fahn (2003).

Tremor is the presenting feature in about three-quarters of the idiopathic cases and consists of alternating contractions of opposing muscle groups (frequency 4–6 Hz). It is present at rest but ceases during sleep, and may become less marked when the limb is engaged in voluntary movement. It is worsened by excitement, anxiety and fatigue.

Most typically it appears in the hands as flexio-extension movements affecting the metacarpophalangeal joints of the fingers and thumb. It is common also in the jaw and tongue and may come to affect the head or the lower limbs. In some cases it is predominantly or entirely unilateral.

Rigidity affects the large and small muscles of the limbs, trunk and neck, involving agonists and antagonists equally and through the whole range of passive movement. In these respects it is quite unlike the spasticity that results from corticospinal tract damage, and feels to the examining hand to have a 'lead pipe' or 'plastic' quality. When tremor is also present, the rigidity is broken up ('cogwheel' rigidity). Rigidity, like tremor, can be predominantly unilateral. It persists during sleep and is unaffected by emotional factors.

Bradykinesia consists of poverty and slowness of movement. This is not due solely to rigidity since stereotactic surgery can relieve rigidity without improving bradykinesia. Bradykinesia is not always sufficiently emphasised in descriptions of the disorder yet can be the most disabling aspect to the patient. Sometimes it dominates the entire picture. It shows in slowness in the initiation and execution of motor acts, and poverty of automatic and associated movements such as the normal swinging of the arms when walking. Fleming (1992) has shown that it can be distinguished from the motor retardation of depression by certain dual task performance tests. Bradykinesia probably accounts for many of the classic features of parkinsonism: the mask-like face, infrequent blinking, clumsiness of fine finger movement, crabbed writing and monotonous speech. The striking disorder of prosody evident in the speech of patients with Parkinson's disease has been shown to be related to motor control, not loss of linguistic knowledge or associated depression (Darkins *et al.* 1988). The gait is affected in many characteristic ways, with slowness, shuffling, difficulty in starting and turning, and impaired equilibrium. It may show an episodic quality, causing periodic freezing of action or episodes of complete immobility. More than any other feature, bradykinesia can be profoundly affected by the patient's mental state. There are numerous reports of severely disabled patients achieving surprising feats of motor behaviour in response to fear, excitement or other environmental stimulation.

Postural changes show as a characteristic flexion of the trunk and neck bringing the chin to the chest, with arms adducted at the shoulders and flexed at elbows, wrists and knuckles. The typical 'festinant' gait appears to be a product of the abnormal posture along with difficulty in controlling the centre of gravity. Postural instability leads to frequent falls.

Other features include oculomotor abnormalities, excessive salivation, seborrhoea, constipation, urinary disturbance, subjective sensory discomfort and marked fatigue. Infrequent blinking is common in all forms of parkinsonism, and paresis of convergence may occur. The latter is par-

ticularly common in postencephalitic parkinsonism, which may also show oculogyric crises. Sialorrhoea is mainly the result of difficulties in coping with normal quantities of saliva on account of dysphagia. Constipation is a major symptom of the disease and a cause of much distress. Urinary frequency and incontinence are frequent complaints. Sensory discomforts include feelings of tightness, pain and cramp in the limbs and back. The fatigue associated with the disorder is often particularly distressing and disabling. It has been found to correlate better with coexistent depression than with the severity of motor symptoms but is often independent of both (Friedman & Friedman 1993).

There has been increased interest in the olfactory dysfunction that is present in 70–100% of patients (Hawkes & Shephard 1998; Katzenschlager *et al.* 2004). Many patients are unaware of a loss of smell but if they are it can predate the onset of motor disturbance by over a year (Henderson *et al.* 2003). As such it may be an aid to early diagnosis.

In the detection of early cases the following observations can be useful. The patient shows difficulty when asked to maintain a steady rhythmic movement, as in tapping or making polishing movements. The handwriting often reveals changes at an early stage, as do attempts to draw parallel lines or spirals. The glabellar tap reflex is elicited by tapping over the root of the nose between the eyebrows; parkinsonian patients are said to blink in response to each tap no matter how often or at what frequency, and fail to habituate as normal subjects do. Observation of the gait can also be revealing in early cases when attention is directed at the lack of arm swinging, difficulty in turning sharply or the exacerbation of tremor in the hands.

Course and outcome

Idiopathic parkinsonism is usually a progressive disease. Difficulties with diagnostic certainty mean studies of prognosis and mortality must be viewed cautiously, although improved treatment has had a definite impact on survival. Life expectancy in well-treated idiopathic Parkinson's disease should be nearly normal. Several studies have found a mortality rate of 1.6 compared with control groups. Mean life expectancy from diagnosis is 14 years. A small number, however, show very slow progression and remain without severe disablement after 20 years or more. Factors associated with increased mortality include advanced age, dementia, depression and lack of levodopa responsiveness. There is evidence that smoking is protective. Common causes of death are cardiac and cerebral vascular disease, bronchopneumonia and neoplasia. The prognosis in terms of rate of progression and mortality is better for postencephalitic cases and worse for vascular parkinsonism and those in whom the diagnosis is unsure since a number of these will ultimately be diagnosed with multiple system atrophy or progressive supranuclear palsy.

Pathology and pathophysiology

Parkinson's disease is associated with lesions in component parts of the extrapyramidal nervous system. The most striking finding is degeneration and loss of neurones in the pars compacta of the substantia nigra, seen macroscopically as nigral pallor. The surviving neurones characteristically show Lewy bodies within their cytoplasm, the pathological hallmark of the condition. These are inclusion bodies with characteristic eosinophilic staining surrounded by a clear halo (Fig. 12.1: see also Plate 12.1). Gibb and Lees (1989) were able to demonstrate Lewy bodies in the remaining pigmented nuclei of the substantia nigra in every case that conformed to strict clinicopathological criteria for idiopathic Parkinson's disease. Lewy bodies consist of ubiquitin and α -synuclein. They are found in other brainstem nuclei, especially the locus caeruleus, raphe nuclei and dorsal vagal nucleus, as well as in the hypothalamus and nucleus basalis of Meynert. In up to one-third of cases they are also apparent in the parahippocampus and temporal neocortex (Gibb & Lees 1987). Glial scarring is seen in the brainstem in the islands from which neurones have disappeared. Cellular degeneration is often apparent in the globus pallidus, putamen and caudate, possibly by virtue of trans-synaptic degeneration. Diffuse cortical atrophy has been reported to be common, and possibly greater than would be expected for healthy individuals of equivalent age. Braak *et al.* (2004) have described six stages through which the pathology of Parkinson's disease progresses. Wider cerebral involvement occurs at each stage. Of note is that in the first two stages symptoms are most unlikely. They suggest that symptoms only arise when a critical degree of neuronal loss, about 70%, has occurred.

In postencephalitic parkinsonism the pigmented cells of the substantia nigra and locus caeruleus are similarly lost, but neurofibrillary changes rather than Lewy bodies are seen in those that remain.

The cardinal biochemical feature of parkinsonism is striatal dopamine deficiency caused by loss of dopaminergic fibres in the nigrostriatal tract, which passes from the pars compacta of the substantia nigra to the caudate and putamen. Consequently, dopamine concentrations in these regions may be reduced to 10–20% of normal levels. The net result is increased inhibitory striatal input to the globus pallidus and thence changes in many parts of the extrapyramidal system, which conspire to produce the parkinsonian picture (Stacy & Jankovic 1992).

The connections of the basal ganglia, and the neurotransmitters involved, are complex and as yet incompletely understood (Stacy & Jankovic 1992; Harding 1993). Multiple parallel loops are present in the extrapyramidal system, two of which predominate. The striatum (i.e. caudate nucleus and putamen) receives glutamatergic projections from all parts of the cortex that pass to their small spiny neurones. These neurones use GABA and a variety of peptides as their neurotransmitters. They project to the lateral globus pallidus and from there to the subthalamic nucleus. This in turn sends glutamatergic projections to the internal segment of the globus pallidus, which projects to the ventrolateral nucleus of the thalamus and back to the cortex.

The second major loop involves GABAergic projections from the striatum to the pars reticulata of the substantia nigra, and dopaminergic projections back from the pars compacta of the substantia nigra in the dense nigrostriatal pathway. The striatum also contains large cholinergic interneurons; dopamine and acetylcholine appear to be

Fig. 12.1 Lewy bodies in the substantia nigra (haematoxylin and eosin). Magnification $\times 600$. (Courtesy of Professor Peter Lantos.) See also Plate 12.1.

antagonistic in their effects in the striatum, and any condition that alters the balance in the direction of marked cholinergic dominance leads to parkinsonism. However, it is clear that dopamine deficiency will also alter the balance of excitatory and inhibitory activity in many parts of the extrapyramidal system, and that the evolution of parkinsonian symptoms will depend on changes in several of its components.

The losses of dopamine in the striatum can be detected by functional neuroimaging. The presynaptic uptake of ^{18}F -labelled dopa by the dopamine transporter is reduced in the caudate and putamen in comparison with age-matched controls, the degree of decline correlating with severity of locomotor disability (Brooks *et al.* 1990). The posterior part of the putamen is most severely affected, with reductions averaging 45% of normal, the anterior putamen and caudate being less markedly involved (62% and 84% of normal levels respectively). This pattern differs from that seen with progressive supranuclear palsy (see Corticobasal degeneration, later in chapter), which shows equally severe reductions in all parts of the putamen and caudate. There is also evidence from studies with ^{11}C -raclopride that the density of D_2 binding sites is slightly upregulated in the putamen in untreated Parkinson's disease, but without change in the caudate (Sawle *et al.* 1990). Studies using single photon emission computed tomography (SPECT) have found that postsynaptic D_2 receptors are preserved, suggesting that only presynaptic fibres are affected in Parkinson's disease. Studies using ^{18}F -fluorodeoxyglucose PET have shown reduced glucose metabolism in the lentiform nucleus contralateral to the affected limb in early disease; much more widespread dysfunction is seen in advanced disease. Colloby and O'Brien (2004) provide a helpful review. Reductions in presynaptic dopamine transporter are also detectable by both SPECT and PET using a number of tropane-based tracers (Brooks *et al.* 2003). These techniques have a sensitivity of around 90% in distinguishing patients with early symptomatic Parkinson's disease from normals and from those with essential tremor and are increasingly becoming part of clinical practice. However, the extent to which a normal dopamine transporter scan might be relied upon to exclude the diagnosis of Parkinson's disease in the presence of symptoms is still uncertain.

In addition to the nigrostriatal pathway, other dopaminergic neurones in the ventral tegmental area of the brainstem project to the cortex and limbic structures. There is evidence that these 'mesolimbic' and 'mesocortical' pathways are also impaired in Parkinson's disease, which may be relevant to some of the psychiatric complications discussed below.

Interesting evidence has recently been obtained concerning the possible origin of the selective degeneration of dopaminergic neurones in the substantia nigra in the disease. The discovery that 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) taken by drug addicts could result

in parkinsonism (Langston *et al.* 1983) has led to the hypothesis that environmental toxins could conceivably play a part. MPTP induces neuronal death via its metabolite, 1-methyl-4-phenyl-pyridine (MPP), which has been shown to inhibit NADH-CoQ₁ reductase (complex I), the first enzyme of the mitochondrial respiratory chain (Nicklas *et al.* 1985). Complex I was then shown to be selectively deficient in the substantia nigra of patients with Parkinson's disease, with normal activities of this and other respiratory chain enzymes in other brain areas (Schapira *et al.* 1989, 1990a,b). No such abnormality was present in patients with multiple system atrophy, which also leads to parkinsonism, suggesting that it may be causally related to Parkinson's disease rather than a consequence of the neuronal degeneration. MPP⁺ is produced by the action of monoamine oxidase B on MPTP; it is taken up by the presynaptic dopamine transporter and is then actively absorbed and concentrated in mitochondria. Inhibition of complex I of the mitochondrial respiratory chain results in the formation of a highly toxic superoxide anion (Zhang *et al.* 2000). MPTP intoxication is now widely used as a model for studying Parkinson's disease.

Additional evidence comes from the finding of abnormalities in sulphur metabolism and *N*-methylation in the disease (Stevenson *et al.* 1989; Green *et al.* 1991). Both reflect deficiencies in the metabolic pathways for removing toxins from the body, suggesting that patients with Parkinson's disease may have been unusually susceptible to environmental toxins with MPP-like activity. Support for such an idea comes from the observation that several environmental toxins can cause parkinsonism, for example carbon monoxide and manganese. Efforts continue to find an environmental toxin that acts in a similar way that might be responsible for sporadic disease. Genetic susceptibility to these or other widespread toxic agents could conceivably play a role in the genesis of the disorder.

There is now increased awareness of the role played by non-dopaminergic neurotransmitter systems in Parkinson's disease. Several strands of evidence point to serotonergic dysfunction. There are reduced serotonergic binding sites in the frontal cortex and basal ganglia (Paulus & Jellinger 1991) and lower levels of the 5-hydroxytryptamine (5HT) metabolite 5-hydroxyindoleacetic acid in the cerebrospinal fluid of patients with Parkinson's disease (Mayeux *et al.* 1988a). Changes in 5HT may be implicated in depression (see Affective disorder, later). Depressed parkinsonian patients have greater neuronal loss from the dorsal raphe, which contains serotonergic neurons, than non-depressed patients (Mayberg *et al.* 2000). Neuronal loss also occurs in the noradrenergic cells of the locus caeruleus (Bertrand *et al.* 1997; Soldani & Fornai 1999). Noradrenergic projections to the frontal cortex are impaired (Everitt *et al.* 1990). These changes would be expected to disrupt attentional processes and Bedard *et al.* (1998) have produced supporting neu-

ropsychological evidence of noradrenergic dysfunction. Improvement in attentional performance followed administration of a noradrenergic agonist. Evidence of a cholinergic deficit comes from a number of areas. Patients with Parkinson's disease show loss of ascending cholinergic projection from the nucleus basalis of Meynert and reductions in neurotransmitter enzymes such as choline acetyltransferase (Perry *et al.* 1985; Rinne *et al.* 1991; Shinotoh *et al.* 1999).

Differential diagnosis

The diagnosis is usually apparent once the disease is reasonably well advanced but mistakes can occur in the early stages, particularly if tremor is absent. In elderly patients the signs may be overlooked and complaints of back or limb pain may lead to a diagnosis of arthritis or osteoporosis. Alternatively, the presentation may be with unexpected falls, which are attributed to vertebrobasilar insufficiency. Strictly unilateral rigidity in the absence of tremor can raise suspicion of a cerebral tumour. Marked bradykinesia may at first raise the question of myxoedema or depressive illness. In patients with evidence of intellectual deterioration the parkinsonian features may be overlooked in favour of a diagnosis of Alzheimer's disease (see Chapter 9).

Rapid fluctuations in the early stages can suggest a psychiatric disorder by way of neurosis, hysteria or even malingering. Such suspicion will be increased if the family reports that the patient can function entirely normally in the face of a stressful situation. In the presence of known psychiatric disorder under treatment with neuroleptic drugs, considerable difficulty may be encountered in distinguishing side effects of therapy from the ingravescent development of idiopathic Parkinson's disease. Here it can be important to remember that the parkinsonian side effects of neuroleptic drugs usually make their appearance early in the course of therapy, then often tend to subside (see first page of chapter). In cases of doubt withdrawal may be necessary for very long periods, sometimes a year or more, before the true situation is clarified.

Benign essential tremor (juvenile, adult or senile: Minor's disease) may lead to difficulties with diagnosis. This can begin at any age, a positive family history is often forthcoming and improvement with alcohol is characteristic. The hands are principally affected, the tremor disappears when the limbs are inactive, and titubation of the head is commoner than in Parkinson's disease. There is no bradykinesia or rigidity and the condition is static or perhaps very slowly progressive over several decades.

Other neurological diseases that must sometimes be considered include Huntington's disease and Wilson's disease. The rigid and akinetic forms of Huntington's disease may at first resemble Parkinson's disease. Wilson's disease must be carefully excluded when parkinsonian symptoms begin in

adolescence or early adult life. The rigidity of Wilson's disease is similar to that of parkinsonism, but the involuntary movements are more varied including choreic jerking, athetoid and dystonic movements, or flapping tremor of the outstretched hands. Other degenerative conditions which must be borne in mind include progressive supranuclear palsy, corticobasal degeneration and multiple system atrophy. Diffuse Lewy body disease may sometimes present with parkinsonian features alone. Hughes *et al.* (1992) found that almost one-quarter of patients diagnosed as suffering from Parkinson's disease are wrongly so labelled: of 100 cases coming to autopsy, 24 had been misdiagnosed, showing the pathological features of progressive supranuclear palsy, multiple system atrophy, Alzheimer's disease or basal ganglia vascular disease. Schrag *et al.* (2002) analysed data on 202 patients who had been diagnosed with Parkinson's disease, prescribed antiparkinsonian medication or who presented with tremor. A diagnosis of Parkinson's disease was correct in 83%; additionally, 19% of those given an alternative diagnosis were subsequently found to have the disease.

Treatment (Fig. 12.2)

In historical terms the aim of treatment has been the relief of symptoms. With the passage of time, questions have arisen about the possible impact of treatment on mortality and whether current treatments such as levodopa may actually be harmful in the long run. Much current research is focused on discovering agents that modify the disease process. As things stand a large proportion of patients can obtain a gratifying degree of relief from their more disabling symptoms, certainly during the earlier stages of the disorder. Some severely crippled patients are enabled to lead relatively independent lives. Specific therapies must be accompanied by general measures to keep the patient active for as long as possible, with physiotherapy or the use of simple mechanical aids. Psychosocial aspects often need attention, especially since the degree of physical disability may be considerably worsened by stress or concurrent depression.

Drugs

Anticholinergic drugs are still used alone in mild cases. The best known are trihexyphenidyl, benztropine (Cogentin®), orphenadrine (Disipal®), procyclidine (Kemadrin®) and biperiden (Akineton). Their effect is variable. Mobility is usually improved, with some decrease in rigidity and tremor. Bradykinesia is usually little affected. Atropine-like side effects limit the dose that can be employed, not least the possibility of revealing or worsening any underlying cognitive impairment. The role of anticholinergic drugs in the management of Parkinson's disease has been the subject of a recent Cochrane Collaboration review (Katzenschlager *et al.* 2003).

Fig. 12.2 The dopaminergic synapse. A, amantadine; ATP, adenosine triphosphate; BA, benserazide; BC, bromocriptine; CL, cabergoline; CD, carbidopa; COMT, catechol-*o*-methyl transferase; D, dopa; DA, dopamine; DD, dopa decarboxylase; DOPAC, 3,4-dihydroxyphenylacetic acid; E, entacapone; HVA, homovanillic acid; LD, levodopa; LU, lysuride; MAO, monoamine oxidase; MAO-B, monoamine oxidase type B; PL, pergolide; PP, pramipexole; R, ropinirole; S, selegiline; T, tyrosine; TH, tyrosine hydroxylase.

Amantadine hydrochloride (Symmetrel®) stimulates dopamine release in the central nervous system, and may be indicated if anticholinergic drugs fail and the patient is only mildly disabled. Among the severely disabled it finds application in patients who cannot tolerate levodopa. Amantadine helps with bradykinesia and postural instability in addition to improving rigidity. Mobility may thereby be considerably improved. Hallucinations and confusion are common side effects. In a recent Cochrane Collaboration review (Crosby *et al.* 2003), all six studies showed a positive effect with amantadine but the poor quality of the data was highlighted. It has also been shown to improve levodopa dyskinesia, although the effects were short-lived (Thomas *et al.* 2004).

Selegiline (deprenyl; Eldepryl®) inhibits monoamine oxidase B, one of the enzymes responsible for the breakdown of dopamine in the brain. It has limited antiparkinsonian action, but when used with levodopa can potentiate and prolong its action, sometimes helping with mild dose-related fluctuations of response. It may also allow the dose of levodopa to be reduced. However, it can sometimes worsen dyskinesias and aggravate psychiatric adverse reactions.

Selegiline became widely regarded as the treatment of first choice for newly diagnosed patients because it proved to be 'neuroprotective' in animals, preventing damage to the

nigrostriatal system when they were exposed to the toxin MPTP (Heikkila 1984). Evidence was obtained from the DATATOP study that Parkinson's disease progressed more slowly in patients who started on treatment with selegiline, in that the need for levodopa was delayed for almost a year in relation to controls (Parkinson Study Group 1989; Tetrud & Langston 1989). This research has been criticised as the improvements may have been due the symptomatic effects of the drug (Horn & Stern 2004). UK findings (Lees 1995) then suggested that selegiline was associated with an increased mortality when used with levodopa. Subsequent analysis of that data could find no clear reason for the increased mortality and in fact when corrected for baseline covariates the significance became borderline (hazard ratio 0.99–1.72) (Ben-Shlomo *et al.* 1998). A more recent meta-analysis of all selegiline trials in early Parkinson's disease has shown no increased mortality (Ives *et al.* 2004). A new preparation of selegiline, Zydis selegiline, avoids first-pass metabolism, and two studies have shown it can improve 'on' time (Shellenberger *et al.* 2000; Waters *et al.* 2004). An alternative monoamine oxidase B inhibitor, rasagiline, is now available.

Levodopa (L-dopa) is now well established as a highly effective drug with a wide range of activity on different parkinsonian symptoms. It would appear a logical form of treat-

ment, L-dopa being the immediate precursor of dopamine that is known to be deficient in the brain, although the precise mechanism of action remains unknown. Approximately one-third of patients can be expected to obtain marked relief, one-third moderate benefit, and the remainder show a modest or disappointing response. Perhaps some 15% do not respond at all; in such cases the possibility of some alternative diagnosis, such as progressive supranuclear palsy or multiple system atrophy, should be considered.

Levodopa is therefore widely regarded as the treatment of choice in patients who can tolerate it. A synergistic action is seen when given in conjunction with anticholinergic drugs and perhaps with amantadine as well. It may take several months before maximal benefit is obtained, and it cannot be said to have failed until it has been tried for 6 months or preferably a year. The variability of response seen from one individual to another cannot yet be accurately predicted.

Levodopa is now always given in combination with a peripheral dopa decarboxylase inhibitor such as carbidopa (in Sinemet) or benserazide (in Madopar). This prevents its metabolism in the gastrointestinal tract, reducing nausea and vomiting, and allows higher blood levels to be achieved with smaller doses. Moreover, the combined preparations increase the turnover of dopamine in the nigrostriatal system more selectively than does levodopa alone, and maximal benefit is obtained earlier.

Concerns have been expressed that long-term L-dopa may be toxic to dopaminergic neurones. Several studies have demonstrated that L-dopa can be harmful to cultured dopaminergic neurones by stimulating the production of highly reactive oxygen species including free radicals (Mena *et al.* 1992; Mytilineou *et al.* 1993). However, the clinical significance of these findings has been questioned. The human brain has high levels of ascorbic acid that acts as an antioxidant. When ascorbic acid is added to culture media, it provides almost complete protection from neurotoxicity (Pardo *et al.* 1993; Walkinshaw & Waters 1995; Cheng *et al.* 1996). *In vivo* animal experiments have largely failed to show L-dopa toxicity. The question was addressed by the ELLDOPA trial in a clinical population (Fahn 2005). No evidence of a detrimental effect from L-dopa was found; in fact there was some evidence that it could be neuroprotective.

Rigidity is helped and tremor also improves but less consistently. Propranolol or some other beta-blocker may further help the latter. Outstanding benefit is seen where bradykinesia and postural instability are concerned, both of which are rarely responsive to anticholinergic drugs. Thus facial mobility is improved, salivation lessened and the voice strengthened. Gait, handwriting and ability to perform fine manipulative tasks all improve. The overall result can be dramatic, with the patient able to do such things as shaving, knitting or getting out of bed unaided when these have not been possible for some considerable time.

Unfortunately, as time goes by the efficacy of levodopa may diminish. In general, over a 5-year period one-third of those who responded initially retain their benefit, one-third lose some and another third lose all their gains becoming worse than they were before (Marsden & Parkes 1977). This is most probably due to progression of the underlying disease. Variations in benefit may emerge for hours or days at a time, or the effects of each dose may become shorter-lasting. The first sign of fluctuation may be early-morning bradykinesia when the effects of the previous day's dose have worn off. End-dose deterioration then appears, with bradykinesia or tremor returning as each dose is due. In time this shows as the 'on-off' effect, with swings from complete relief to total immobility, often occurring with startling rapidity and sometimes many times a day (Marsden & Parkes 1976). By this time, peak-dose dyskinetic movements have also usually developed. In extreme form the patient may be precipitated within minutes, or even seconds, from a state of dyskinetic mobility to one of profound rebound parkinsonism (Quinn 1995).

Tests carried out serially during on and off phases have shown some mild impairment of cognition and adverse swings of affect during the latter phases (Brown *et al.* 1984). In a detailed study of nine patients experiencing severe on-off phenomena, Nissenbaum *et al.* (1987) found that four had clear-cut depression and anxiety when 'off', one also showing features of elation and disinhibition when 'on'. In a questionnaire survey, two-thirds of 31 such patients reported some degree of parallel mood change, usually towards depression when akinetic but also with feelings of irritability, aggressiveness and frustration. In rare cases hallucinations and delusions may accompany the transient depressions.

A 69-year-old woman on treatment with Sinemet progressed after 7 years to severe and abrupt changes characteristic of the on-off phenomenon. One year later she began to experience parallel fluctuations in mood. In the 'off' condition she showed depressed mood, agitation, hypochondriacal and nihilistic delusions, and an unshakeable belief that something dreadful was about to happen. She had ideas of guilt, and auditory and visual hallucinations. Although agitated she remained fully orientated and could retain information provided her attention could be sustained. In this condition she was chair-bound. When mobile and 'on' she had a mildly depressed mood, but was not agitated, deluded or hallucinated, and had partial insight into the psychotic phenomena experienced when immobile (Nissenbaum *et al.* 1987).

A 35-year-old man who had taken Sinemet for 4 years developed manic features during 'on' phases alternating with depression when 'off'. During 'on' phases he showed choreoathetoid movements and became overactive and talkative. He was extremely elated and expressed grandiose ideas that he would marry several women and live for 100 years. On reverting to severe immobility he showed profound depression and nihilistic thought content and expressed the wish to be dead. Between the fluctuations in mood and movement he improved, exhibiting neither mood abnormalities nor dyskinesias. There was no past or family history of affective disorder. His condition was ameliorated by giving smaller doses of medication more frequently (Keshavan *et al.* 1986).

Considerable improvement may be obtained by giving the drug in small divided doses, even every 2 or 3 hours through the day, or by the use of sustained-release preparations. Other approaches are to add selegiline, or to partially substitute an agonist drug such as bromocriptine or pergolide. Apomorphine can find a special place in the treatment of refractory on-off oscillations as described below.

Adverse effects commonly include anorexia, nausea, vomiting and hypotension. These can usually be overcome by starting with low dosage and increasing very gradually. The gastrointestinal effects can be largely avoided by the use of combined preparations of levodopa with a selective extracerebral decarboxylase inhibitor (Sinemet or Madopar). Tremors, tachypnoea, flushing and cardiac dysrhythmias may also be troublesome.

The commonest dose-limiting factor is the appearance of dyskinesic movements. Such dyskinesias can take any form, including orofacial dyskinesia, chorea, dystonia or athetosis of the limbs, analogous in form, and probably in pathophysiology, to the movements seen in tardive dyskinesia (see Drug-induced disorders/Clinical pictures/Akathisia, earlier). Three main varieties are recognised: peak-dose dyskinesia, with choreic or dystonic movements; diphasic dyskinesia, which occurs at the beginning and end of the dose and is often ballistic in character; and 'off-period' dystonia, with fixed, often painful, spasms mainly involving the feet. A compromise quite often has to be sought between the severity of such adventitious movements and the degree of relief of parkinsonian disability. Levodopa produces motor complications at the rate of 10% per year (Quinn *et al.* 1986). Olanow *et al.* (1994) has described how the onset of dyskinesias depends on the state of the nigrostriatal neurones. In MPTP models of the disease, there can be 95% neuronal loss; in this situation, dyskinesias can appear within days. In older patients with advanced disease, dyskinesias appear in months although in general they take many years.

Historically, treatment has started with levodopa and then been adjusted to include dopamine agonists as levo-

dopa dyskinesias appear. Recent consideration has been given to delaying the onset of dyskinesias. Two studies have examined the use of slow-release preparations but failed to show any difference (Dupont *et al.* 1996; Block *et al.* 1997). An alternative approach is to start treatment with a dopamine agonist and several randomised controlled trials have examined this issue (Rinne *et al.* 1998; Parkinson Study Group 2000; Rascol *et al.* 2000). Initial treatment with a dopamine agonist was associated with delay in the onset of dyskinesias and other motor complications, although this was to some degree offset by clear evidence that those whose treatment commenced with levodopa had a better clinical response. There remains debate as to the optimal approach (Albin & Frey 2003).

Bromocriptine acts as a direct stimulant of dopamine receptors. Only about one-third of patients obtain a response to bromocriptine alone, but when given with levodopa it allows a smaller dose of the latter to be employed. Some prefer to use it initially on its own in order to defer the introduction of levodopa with its attendant long-term risks of fluctuation in response and dyskinesias. Early combination therapy with levodopa and bromocriptine has some advocates. It finds a special place in the management of patients who experience fluctuations in response to levodopa as described above.

Bromocriptine must be used with caution in the presence of peripheral vascular disease since it is derived from ergot, and it is contraindicated in the presence of ischaemic heart disease. Postural hypotension can be a problem when starting treatment, also nausea and vomiting, which are helped by domperidone. Psychiatric side effects are similar to those seen with levodopa (see Drugs, earlier).

Other dopamine agonists include cabergoline, lisuride, pramipexole, pergolide and ropinirole. Their role in the management of Parkinson's disease has been reviewed by the Movement Disorders Society Task Force (2002). Pergolide, ropinirole and pramipexole have all been studied in early disease. They appear equally effective and are less likely to lead to dyskinesias, although as noted above they do not produce the same clinical improvement as levodopa. They all appear to be effective as adjunctive treatments (Cochrane library issue 2004), reducing 'off' time and improving motor impairments and activities of daily living. Pergolide and cabergoline are ergot-derived drugs and their use is associated with serosal reactions such as retroperitoneal fibrosis. In one study valvular heart disease was demonstrated in one-third of patients taking pergolide (Van Camp *et al.* 2004). There is some evidence that dopamine agonists have a neuroprotective disease-modifying action. The CALM-PD trial studied pramipexole over 4 years and showed significantly reduced decline in striatal neurone loss assessed with SPECT (Parkinson Study Group 2002). The REAL-PET study showed lower decline in ^{18}F -labelled dopa in patients taking ropinirole (Whone *et al.* 2003).

However, the methodologies of both studies have been criticised (Clarke & Guttman 2002; Wooten 2003) and to date neither drug is licensed as 'disease-slowing' in Parkinson's disease.

Apomorphine has a special place in the treatment of late-stage fluctuations in response to levodopa when other approaches have failed, and can on occasion be life-saving (Stibe *et al.* 1988; Hughes *et al.* 1993). It is also a D₁ and D₂ receptor agonist but must be given by subcutaneous injection. Oral domperidone is given concurrently to prevent vomiting. Patients and their relatives can be instructed to inject the drug when 'off' periods occur, relief occurring within 15 minutes and lasting for up to an hour. Continuous daytime infusion can be achieved through a portable pump. Long-term use appears safe and effective (Manson *et al.* 2002; Tyne *et al.* 2004). The injections work with high reliability and tolerance does not develop, but drowsiness and local reactions at injection sites can be troublesome. Intranasal apomorphine is currently being developed as an alternative (Koller *et al.* 1997; Dewey *et al.* 1998).

Catechol O-methyltransferase (COMT) is one of the enzymes that metabolise L-dopa and dopamine. Entacapone inhibits COMT peripherally, thus increasing the availability of both dopamine and L-dopa. Another drug, tolcapone, has been withdrawn. Entacapone appears effective as adjunctive therapy, having the advantage over dopamine agonists that it does not need titration (Parkinson Study Group 1997). A new combination drug (containing levodopa, peripheral decarboxylase inhibitor and entacapone) was appreciated by patients and improved compliance (Myllyla *et al.* 2003). A possible additional benefit of the combined use of entacapone and levodopa may be that levodopa pulsatility, believed to contribute to the onset of motor complications, is reduced (Smith *et al.* 2005).

Surgery

There have been considerable developments in the surgical management of Parkinson's disease. The best results are seen in patients with true idiopathic disease who have had dopamine-responsive symptoms (Walter & Vitek 2004). Goals of surgical treatment may be core symptoms of the disease or drug-induced motor complications. Lesions in the ventral intermediate nucleus of the thalamus are effective in relieving tremor, including essential tremor (Walter & Vitek 2004). However, bilateral disease requires bilateral thalamotomies. Alvarez *et al.* (2001) showed a 58% improvement in 'off' medication motor scores 2 years after bilateral thalamotomy. Postoperative chorea was common but short-lived. Bilateral thalamotomies carry the risk of adverse events such as speech problems or gait disturbance (Matsumoto *et al.* 1976; Speelman 1991). Deep brain stimulation is an alternative to lesioning. Again, bilateral stimulation appears more effective than unilateral stimulation (Ondo *et al.* 2001) but dysarthria can be a problem (Walter &

Vitek 2004). One study has compared thalamic lesions to thalamic stimulators (Schuurman *et al.* 2000). Both were equally effective in terms of tremor control but lesions were associated with more adverse events. Matsumoto *et al.* (1984) and Wester and Hauglie-Hanssen (1990) argue that stimulation-related side effects can be reversed, but lack of effect on non-tremor symptoms has limited the use of the thalamic approach (Benazzouz *et al.* 2002).

Two randomised controlled trials confirmed that pallidotomy can improve contralateral tremor, rigidity, bradykinesia and drug-induced dyskinesias (de Bie *et al.* 1999; Vitek *et al.* 2003). In the study by de Bie *et al.* (1999), gait and postural benefits had been lost at 1 year follow-up, although in the study by Vitek *et al.* (2003) significant benefits in ipsilateral rigidity, bradykinesia and drug-induced dyskinesias were still present at 2 years. Surgical complications with bilateral pallidotomy include hypophonia, dysarthria and cognitive problems (Favre *et al.* 2000; Intemann *et al.* 2001; Merello *et al.* 2001; de Bie *et al.* 2002).

Neural transplantation has been shown to be successful in restoring function in primates with lesions of the dopamine pathways, and limited experience has been obtained in patients with Parkinson's disease (Hitchcock 1992; Lindvall 1994; Hauser *et al.* 1995). Despite occasional reports of striking success with autologous transplantation of tissue from the adrenal medulla, this approach has proved disappointing and the use of fetal dopaminergic cells appears to hold more promise. However, this raises considerable ethical problems.

Adrenal medullary transplantation seems commonly to be followed by behavioural complications in the immediate postoperative period, including sleep disturbance, hallucinations, delusions, confusion and mood changes (Stebbins & Tanner 1992). Techniques of this nature may yet find a place in the management of younger patients whose disease is difficult to control by other means, but continuing improvements in drug therapy may overtake their further development.

Psychiatric aspects of parkinsonism

Interest in the psychiatric aspects of parkinsonism has increased as a result of advances in knowledge of the disease. The advent of stereotactic surgery focused renewed attention on the problem of intellectual impairment in the disorder, and the demonstration of disturbance of amine metabolism has brought new interest to its association with depression.

There is a good deal of disagreement in different reports regarding the frequency of mental symptoms, undoubtedly depending on the particular population under scrutiny. Thus behavioural disturbance is likely to be more common when a substantial number of postencephalitic cases are examined, and intellectual impairment will be more

frequent when patients with 'arteriosclerotic parkinsonism' are included in the sample. The difficulties of achieving anything like a reliable estimate are increased by the problems inherent in distinguishing these different varieties one from another.

Mjones (1949) reviewed the earlier work in detail. Three main groups of mental disturbance gradually came to be recognised and were sometimes regarded as an integral part of the pathological picture: a change of personality towards suspicion, irritability and egocentricity; an impairment of memory and intellect; and psychotic developments with depression, paranoia and sometimes visual hallucinations. Some felt that there was a typical paralysis agitans psychopathy, others a characteristic psychosis. Some found a great excess of dementia, others of depression. Mjones' own investigation of 262 cases of paralysis agitans revealed mental symptoms in approximately 40%. 'Organic' changes predominated over 'reactive' changes, the former consisting of impaired memory and intellect, the latter of depression with irritability, egocentricity and hypochondriasis. Transitional forms were also encountered in which the relative contributions of organic or reactive elements were uncertain.

More recent studies have served to underline the associations with depression and cognitive impairment, the latter chiefly in later-onset Parkinson's disease. It now seems indubitable that the risk of dementia is increased above expectation and several hypotheses have been advanced to account for this. A typical personality change, or a characteristic form of psychotic reaction, are no longer recognised. Those psychoses that do emerge are largely seen in the context of treatment with levodopa and other drugs. These matters are dealt with in detail in the sections that follow.

Cognitive impairment and dementia

The question of cognitive impairment in Parkinson's disease has attracted a great deal of interest, particularly since the advent of treatments that may be effective in prolonging life. There is no doubt that some patients show impairment of cognitive function, sometimes severe and pervasive enough to amount to an easily recognised progressive dementia. Others in contrast remain intellectually intact despite gross physical disablement. The issue which has been hard to resolve is whether, as a group, patients with idiopathic Parkinson's disease are more prone to develop such difficulties than would be expected by virtue of their age alone. The present consensus is that the risk of dementia is definitely increased, perhaps some two- or three-fold. Possible reasons for this have turned out to be complex, and are gradually being disentangled as discussed below.

Brown and Marsden (1984) review the differing estimates of the prevalence of dementia in Parkinson's disease, ranging from 10% to over 80%, and the possible reasons for such wide discrepancies.

Sampling errors are compounded by difficulties in excluding other causes of akinetic-rigid syndromes during life, particularly in separating idiopathic Parkinson's disease from 'arteriosclerotic parkinsonism' (see under Parkinson's disease and the parkinsonian syndrome, earlier). If some examples of parkinsonism merely reflect an accent of diffuse cerebral vascular disease on the basal ganglia, then the cognitive impairments encountered could be due to the widespread cerebral changes in this group. On the other hand, when cognitive impairment is used as a criterion for separating arteriosclerotic from idiopathic parkinsonism, the idiopathic cases will tend to be reported as intact.

Problems with the definition and assessment of dementia are also considerable, and the criteria employed have varied from one study to another. Some have sought to identify the clinical syndrome of dementia, using behavioural criteria and brief mental state tests, whereas others have used batteries of psychological tests to look for specific cognitive deficits. With both approaches the assessment of parkinsonian patients can raise special difficulties. Behavioural criteria must allow for the curtailment of activities occasioned by the disease; psychological testing must take into consideration slowness of response, which may be largely attributable to motor handicap. Care must be taken to allow for what is to be expected in any ageing group of persons, and to differentiate cognitive failure from the depression common with Parkinson's disease. Drugs taken for treatment of the condition may further complicate assessments.

An impressive early survey was carried out by Marttila and Rinne (1976) involving all traceable patients with Parkinson's disease in a defined area of Finland. Of 144 patients, 29% were thought to be demented, 50% of these being mildly, 30% moderately and 20% severely affected. Patients with evidence of arteriosclerosis were more often demented than those without (56% and 18% of cases respectively). There was a clear rise with age, from 20% among those under 70 to 65% among those over 80. The severely physically disabled showed dementia more often than the mildly affected, with increasing severity of rigidity and bradykinesia showing a positive correlation with the degree of intellectual decline. This association pointed to a role for subcortical structures in the pathophysiology of the dementia.

Lieberman *et al.* (1979) found moderate to marked dementia in one-third of 520 patients, this being 10 times the prevalence in spouses used as controls. The demented patients, in addition to a later onset, had become more physically disabled in a shorter time and had responded less well to levodopa. Two distinct forms of Parkinson's disease, with and without dementia, thus seemed a possibility. Lees and Smith (1983) restricted attention to mildly disabled patients, all under the age of 65 and with normal CT scans. Comparisons with age-matched controls showed no impairment on tests of intelligence or memory, but revealed significant deficits on the Wisconsin Card Sorting Test and a verbal fluency test. Frontal cognitive deficits were therefore highlighted.

More recent surveys have attempted to allow for the various sources of artefact outlined above, in particular adopting stringent criteria for the diagnosis of dementia.

The great majority have confirmed an increased prevalence of dementia in the disease. Rajput *et al.* (1984) reviewed the Mayo Clinic records of all parkinsonian patients seen over a 13-year period, charting dementia only when this had been diagnosed on at least two separate occasions. For every patient, two sex- and age-matched controls were selected from residents in the area. Of the 138 new parkinsonian patients seen, 13 (9.4%) were demented compared with 2.9% of controls. When none of the three matched individuals showed dementia at the time the parkinsonism was first recognised, these were followed further and dementia emerged more frequently among the patients than the controls.

Mayeux *et al.* (1988b) performed a similar review of records from a medical centre in New York. Among 339 patients with idiopathic Parkinson's disease, 10.9% were demented according to DSM-III criteria. The demented patients were significantly older than the remainder, had a later age of onset and a more rapid progression of physical disability. When the parkinsonism had begun after the age of 70, dementia was noted almost three times as often as when the onset had been earlier. Among patients over 60 years old the prevalence was judged to be almost four times that expected for a population of equivalent age. Equivalent results were obtained from a register-based survey of patients in the Netherlands, incepted with a hospital discharge diagnosis of Parkinson's disease and followed an average of 8 years later (Breteler *et al.* 1995). In comparison with a reference group of patients with non-cerebral diseases, the risk of developing dementia during this period was increased threefold.

The most clear-cut evidence, however, has come from Mindham's group, who have reported the first truly prospective study of dementia in idiopathic Parkinson's disease (Biggins *et al.* 1992).

Serial assessments were made of cognition, mood and level of disability in a group of 87 patients and 50 healthy matched controls over a 4.5-year period, each subject being examined at 9-month intervals. The mean age of the patients was 64 years. Patients were excluded if they had a history of stroke, hypertension or transient ischaemic attacks, or when there were indications of other neurological disorder. An extensive battery of psychometric tests was administered at each examination, along with rating scales for depression, anxiety and physical disability. The accumulated data sheets were reviewed at the end of the study, blind to whether the subject was a parkinsonian patient or control, and diagnoses of dementia were made according to DSM-III criteria. Judgements were made as to the assessment at which these criteria were first satisfied.

Of the 87 patients, five (6%) were considered to have been demented from the outset of the study, and 10 more became demented during the follow-up period. No control subject did so. After allowing for patients who dropped out during the course of the survey, the cumulative incidence of dementia over this period was 19%. Comparisons between those who demented and those who did not showed that the former were older, older at onset of Parkinson's disease, had a longer duration of illness, and had lower initial performance on certain cognitive tests. This last might indicate that their dementia

had already been present in milder form while not yet meeting DSM-III criteria.

It therefore seems clear that dementia, identifiable clinically, is increased above expectation in Parkinson's disease, even when care has been taken to exclude vascular and other pathologies that might have contributed towards it. Cognitive impairments, insufficient in themselves to lead to such a diagnosis, seem also to be common, though there is insufficient information to judge how often these may be a prelude to dementia.

Psychometric studies show a wide spectrum of deficits among cognitively impaired parkinsonian subjects, as reviewed by Ross *et al.* (1992). In some the picture resembles 'subcortical dementia' (see Chapter 1 under Clinical picture in focal cerebral disorder/Basal ganglia), particularly with respect to memory functioning, and executive function deficits are often prominent suggesting disruption of frontal-subcortical connections. In others, however, there are language and other impairments that point to cortical dysfunction. Sometimes, indeed, the clinical picture appears to overlap with that of Alzheimer's disease. Ross *et al.* conclude that the heterogeneity of the pictures seen suggests that there are multiple dementia syndromes in Parkinson's disease, associated with varying structural and biochemical pathology.

The causation of these deficits remains uncertain and a number of possibilities must be considered. First, they may be due in part to the classic pathology of Parkinson's disease and the dopamine deficiency that ensues. The subcortical nature of the dementia in many examples would fit with such a pathogenesis, especially since mesolimbic and mesocortical projections are known to be involved along with disruption of the nigrostriatal system. Such projections arise from the medial substantia nigra and the ventral tegmental area, and these have been found to be particularly severely affected in parkinsonian patients with dementia (Rinne *et al.* 1989). Neuronal counts and noradrenaline (norepinephrine) levels have also proved to be reduced in the locus caeruleus in the presence of dementia, suggesting that diminished noradrenergic inputs to the cortex may make an additional contribution (Gaspar & Gray 1984; Chui *et al.* 1986; Cash *et al.* 1987). Together these observations support a subcortical origin for the dementia.

To a notable degree, however, dementia is rare in younger patients with Parkinson's disease, even though in all other respects the course and pathology of the disorder appears to be similar whatever the age of onset (Gibb 1989). Dementia has emerged as exceptional with onset below the age of 50, even with disease of long duration, and it becomes commoner with later onset, especially after 70 years. Indeed the factor of age of onset has emerged as one of the firmest risk factors for the development of dementia.

With age there is increasing likelihood of finding Alzheimer-type pathology in the cortex, and certain studies

have suggested that this may play a major role in producing the dementia. Alvord *et al.* (1974) and Hakim and Mathieson (1978, 1979) found Alzheimer changes to be commoner in patients with Parkinson's disease than in age-matched controls, and Boller *et al.* (1980) found the prevalence of plaques and tangles in the cortex to rise as the severity of dementia increased. A cortical pathology of Alzheimer type might thus be accelerated in the presence of Parkinson's disease and account for the cognitive deficits seen. However, further detailed studies have given conflicting results and this hypothesis is now regarded as uncertain (Jellinger & Riederer 1984; Gibb 1989).

A third possible explanation involves the nucleus basalis of Meynert. Perry *et al.* (1985) demonstrated marked cholinergic deficits in the cerebral cortex of parkinsonian patients, which in the temporal neocortex correlated with the severity of mental impairment assessed prior to death. The cholinergic deficits were of a similar order to those seen in Alzheimer's disease, despite the dementia being milder, but lacked correlation with the degree of tangle and plaque formation. Rather they correlated with the extent of neuronal loss in the nucleus basalis of Meynert. This was always pronounced, with losses of up to 70% in the presence of parkinsonian dementia. Thus the cortical cholinergic deficits seemed not to be explicable in terms of cortical pathology, but more probably resulted from degeneration of cholinergic axons associated with the loss of cells in the Meynert nucleus. Such loss might itself be due to a pathological process analogous to that inducing changes in the substantia nigra.

This striking set of observations has been both confirmed and refuted in other studies, as reviewed by Ross *et al.* (1992) and Chui and Perlmutter (1992). And it has become apparent that, at least in some cases, dementia can occur in Parkinson's disease in the absence of either Alzheimer-type pathology in the cortex or cell loss in the nucleus basalis of Meynert.

These various possible contributions to dementia are discussed in detail by Dubois and Pillon (1992). It seems probable that many of the cognitive changes are largely due to subcortical pathology, with dopamine deficiency being compounded by loss of inputs from noradrenergic and cholinergic nuclei. In the older patient with Parkinson's disease and severe dementia, concomitant changes of Alzheimer type in the cortex are likely to make an additional contribution.

Structural brain imaging has not contributed substantially to this cortical/subcortical debate. Air encephalography (Selby 1968) and CT (Sroka *et al.* 1981) have shown a high prevalence of cerebral atrophy in patients with Parkinson's disease, and in several studies ventricular enlargement has correlated with the presence of cognitive impairment (Huber & Glatt 1992). Third ventricular width and the intercaudate distance have also shown such associations, whereas the contribution of cortical atrophy usually disappears on controlling for age. To this extent structural imaging supports the relevance

of subcortical pathology. Magnetic resonance imaging has not clarified the situation further (Huber *et al.* 1989).

PET and SPECT have in contrast tended to underline the importance of cortical pathology, showing deficits in metabolism in the frontal and parietal regions that are marked in the presence of dementia. Metter *et al.* (1990), using fluorodeoxyglucose-PET, found essentially the same pattern of hypometabolism in parkinsonian dementia and Alzheimer's disease, with global reductions in brain metabolism and an accent on the parietal regions. These could be observed to progress with worsening of the cognitive impairment. Peppard *et al.* (1992) showed widespread cortical and subcortical reductions in glucose metabolism in non-demented parkinsonian patients, though with significant further reductions in the cortical regions in the presence of dementia. The temporoparietal regions were again particularly affected. It remains unclear, however, whether such patterns reflect intrinsic cortical pathology or the cortical effects of deafferentation from subcortical structures.

Finally, a fourth element has been added now that it is appreciated that Lewy bodies are often found in the cerebral cortex as well as in brainstem nuclei. How far diffuse Lewy body disease may make its own contribution to cognitive failure in patients with Parkinson's disease remains to be determined, but no doubt this may operate as a substantial additional factor.

Affective disorder

An association between parkinsonism and depression is well established. However, debate continues on whether depression is best seen as an understandable response to a debilitating disease or is part of the disease process itself.

Estimates of the prevalence vary widely between 5% and 90% (Hoehn & Yahr 1967; Mindham 1970; Tandberg *et al.* 1996). Early studies have limited validity in light of changes to the diagnostic criteria for both depression and Parkinson's disease. Most notably, early studies tended to use a clinical interview to assess depression rather than a standardised tool. Starkstein *et al.* (1990) assessed 105 patients using the Present State Examination (Wing *et al.* 1974) to produce DSM-III diagnoses; 21 patients had 'major' depression and 20 'minor' depression. Cummings (1992a) suggested a figure of 40%, including both 'major' and 'minor' depression in a single category.

The nature of the population being studied has a great bearing on the findings. Tandberg *et al.* (1996) assessed a large community sample in Norway and found that only 8% had major depression although 45% had depressive symptoms. Studies involving patients who attend specialist clinics identify higher prevalences. Liu *et al.* (1997) found that 17% of patients attending a neurological clinic had major depression, with a further 25% having milder symptoms. Schrag *et al.* (2001) found that 20% of their patients attending a specialist clinic had moderate or severe depression. The precise status of 'mild' or 'sub-syndromal' depression is yet to be determined – the exact point at which a

patient can be labelled 'depressed' is of course somewhat arbitrary. However, there is increasing evidence that patients with depressive symptoms who fail to meet current diagnostic criteria for major depressive disorder nonetheless suffer a degree of psychosocial dysfunction as a result of these symptoms, are more likely to have a major depressive episode in the future and can benefit from intervention (Judd *et al.* 2002). Thus, all depressive symptoms warrant careful clinical appraisal.

A number of possible risk factors, such as age, sex, disease duration and duration of levodopa treatment, are not consistently found to predict depression in Parkinson's disease. Fleming (1991) showed that depression and anxiety were both more common when unilateral Parkinson's disease affected the left rather than the right side of the body, and noted this to be the reverse of what might have been expected if the symptoms were purely a response to functional disability. However, other studies found depression more often in patients with right-sided disease (Starkstein *et al.* 1990; Cole *et al.* 1996). Early disease onset (Kostic *et al.* 1994; Cole *et al.* 1996), a positive family history of depression (Tandberg *et al.* 1997) and atypical parkinsonian signs such as prominent autonomic signs or presence of pyramidal symptoms or rapidly progressive disease (Quinn *et al.* 1986) appear better predictors. Several authors report an association with cognitive impairment (Tandberg *et al.* 1996; Schrag *et al.* 2001; Rojo *et al.* 2003; Lauterbach 2004). Starkstein *et al.* (1989) have suggested that these may cluster together as a subtype of Parkinson's.

A great deal of discussion has surrounded the possible association between disease severity and depression. In individual patients depression can sometimes be clearly reactive in nature, setting in immediately the patient is informed of the nature of the disease, or developing later as an understandable response to the limitations and discomforts imposed by physical disability. Mindham (1974), for example, was able to show a significant correlation between the severity of the leading signs of parkinsonism and the severity of depression in a group of patients attending a neurological clinic. This relationship persisted during treatment with levodopa, those improving physically showing a fall in the severity of affective symptoms. However, the findings of other studies (reviewed by Brown & Jahanshahi 1995) fail to support this simple model.

Starkstein *et al.* (1990) compared rates of depression with stage of disease (as determined by Hoehn and Yahr's method) and found an inverted U-shaped curve, with depression being more common in the early and late stages of the disease. This finding has been replicated by Schrag *et al.* (2001). Hoehn and Yahr stages may be a coarse measure of function and further studies have examined the association of depression with disability and handicap. In this context, impairment relates to the objective disease severity, whilst disability reflects the functional impact of that disease

severity for the individual and handicap describes the broader disadvantages perceived by the individual, for example in being able to fulfil particular roles. Brown *et al.* (1988) demonstrated an association between depression and disability but not simple disease impairment. Schrag *et al.* (2001) found that disease severity accounted for only 28% of the variance in depression but handicap predicted more than 50% of this variance. In other words, depression relates not solely to what an individual patient can or cannot do but more to what such impairments mean for that individual within his own personal social environment.

However, there are also indications that depression may sometimes bear a more integral relationship to the disease process itself, reflecting in some way the causative brain pathology. The high prevalence of depression has impressed many observers and it has seemed to be commoner than in equivalently disabling illnesses (Warburton 1967; Horn 1974; Singer 1974). Robins (1976), for example, supported such an interpretation. In a carefully controlled study, 45 patients with Parkinson's disease were matched for age and sex with chronically disabled people drawn from the same institutions (patients with hemiplegia, paraplegia and arthritis). The groups resembled each other with regard to the frequency of a pre-illness history of depression or of neurotic symptoms. The duration of disablement was similar in both but the degree of handicap greater in the non-parkinsonian group. Nevertheless, the patients with Parkinson's disease were significantly more depressed than the controls as measured by the Hamilton rating scale. In neither group did the severity of disability affect the presence or absence of depression, suggesting that the latter was not solely reactive in nature. However, Gotham *et al.* (1986) found that depression was as common in rheumatoid arthritis as in Parkinson's disease. A growing body of evidence supports the suggestion that at least a proportion of the depression seen in Parkinson's disease is an expression of the disease itself. One piece of this evidence comes from the observation that rather than being a reaction to the disease, depression commonly precedes the emergence of parkinsonian motor symptoms (Santamaria *et al.* 1987; Fukunishi *et al.* 1991). Goner *et al.* (1997) suggest that depression may be part of a prodromal syndrome occurring 4–6 years ahead of the motor symptoms. Shiba *et al.* (2000) used a medical records linkage system to overcome some of the problems associated with recall bias. In their sample the odds ratio for a preceding diagnosis of depression in parkinsonian patients was 1.9 compared with controls.

Noradrenergic and serotonergic abnormalities are strongly associated with depression in non-parkinsonian patients. Widespread degeneration of monoaminergic neurotransmitter systems are known to occur in Parkinson's disease (Fibiger 1984; Mayeux *et al.* 1984; Lemke *et al.* 2004). Remy *et al.* (2005) showed that depressed patients have reduced catecholaminergic transport in the locus caeruleus,

thalamus, striatum and amygdala, and particularly highlighted that loss of noradrenaline and dopamine in the amygdala may contribute to depressive symptomatology. Weintraub *et al.* (2004) used SPECT to show that depressed patients had decreased dopamine transporter availability in the left anterior putamen.

Other studies have focused on the frontal areas of the brain. Taylor *et al.* (1986) showed that depressed parkinsonian patients showed greater impairment on frontal lobe testing than non-depressed patients and suggested that depression was associated with abnormalities in the links between the caudate and the frontal lobe. Mayberg *et al.* (1990) showed reduced glucose metabolism in the orbital and inferior frontal areas of depressed patients, whereas Ring *et al.* (1994) demonstrated reduced regional cerebral blood flow in the anteromedial part of the medial frontal cortex. This area has already been associated with depression in non-parkinsonian patients (Bench *et al.* 1992).

In a large postal survey, Gotham *et al.* (1986) were able to show that depression was related to the degree of impairment in activities of daily living, but even so much of the variability was left unaccounted for. Individual differences in coping style and the availability of social support were probably also influential. The symptom profiles observed included pessimism, hopelessness, decreased motivation and increased concern over health; in contrast, guilt, self-blame and worthlessness were usually absent.

Several studies allude to phenomenological differences between depression in parkinsonian and non-parkinsonian patients. Lemke *et al.* (2004) suggests that parkinsonian depression is characterised by increased levels of dysphoria and irritability and lower levels of guilt and suicidality. In another study, Lemke *et al.* (2005) found marked anhedonia in 80% of depressed parkinsonian patients.

Increased tearfulness has been found to be common in patients with Parkinson's disease, sometimes with 'emotionalism' as indicated by sudden weeping with loss of normal social control (Madeley *et al.* 1992). Almost half of a group of patients with idiopathic Parkinson's disease reported being more tearful since the onset, and 10% showed emotionalism of the type following cerebrovascular accidents (Chapter 8). Such disturbances were sometimes evident in the absence of lowered mood or cognitive impairment.

One obvious problem in the assessment of depression in Parkinson's disease is deciding if 'somatic' features such as slowness and paucity of facial expression are due to the depression or the disease. As a result there has been interest in the use of screening questionnaires. Levin *et al.* (1988) studied the Beck Depression Inventory (Beck *et al.* 1961) using cluster analysis and showed that the somatic questions 'scored true' rather than producing large numbers of false positives. However, Leentjens *et al.* (2000a) has drawn attention to the limitations of the Beck Depression Inventory. In their study, a cut-off of 8/9 gave high sensitivity but

low specificity, i.e. too many false positives. It was not until the cut-off was raised to 16/17 that the specificity was acceptable, but at the expense of the sensitivity, i.e. too many missed cases. Meara *et al.* (1999) have used the Geriatric Depression Scale but found the somatic elements did overscore, producing an excess of false positives. Leentjens *et al.* (2000b) compared the Montgomery-Asberg Depression Rating Scale and the Hamilton Depression Rating Scale, using the Schedule for the Assessment in Neuropsychiatry to provide DSM-IV gold standard diagnoses. The Hamilton Depression Rating Scale appeared to perform better.

Depression impacts substantially on the patient with Parkinson's disease. Physical symptoms progress more quickly in depressed patients (Starkstein *et al.* 1992a); for example, Rochester *et al.* (2004) showed that depression was independently associated with a reduced speed of walking during functional tasks. Brown *et al.* (1988) and Starkstein *et al.* (1992a) reported greater decline in self-care in depressed patients. Starkstein *et al.* (1992a) demonstrated that cognitive function declined more quickly in depressed patients over a year, and that the decline was greatest in the most depressed patients. Previously Starkstein *et al.* (1990) observed that the decline in Mini Mental State Examination scores in patients treated for depression was about half that of untreated controls. Two large studies have examined the factors which contribute to overall health-related quality of life in Parkinson's disease. Kuopio *et al.* (2000) found that patients' Hoehn and Yahr stage accounted for 48% of the variance in their scores on the physical function domain of the SF36, followed by depression. For all of the other seven domains, depression was the strongest predictor. The Global Parkinson's Disease Survey examined patients in seven countries (Global Parkinson's Disease Survey 2002); knowing the disease stage and the medication the patients were taking explained 17% of the variance in quality of life, whereas depression measured on the Beck Depression Inventory accounted for more than 50%.

Patient depression can have an adverse impact on the spouse or carer (Lawton *et al.* 1995). Carers of patients with Parkinson's disease have a heavy burden, performing up to 30 care-related activities per day. Carter *et al.* (1998) and O'Reilly *et al.* (1996) found five times the level of psychiatric illness in spouses who were carers compared with spouses who were not main carers. Meara *et al.* (1999) also reported high levels of depression in carers of parkinsonian patients, the best predictor of which was depression in the patient.

Early research on levodopa's effects examined whether it had an antidepressant effect. Yahr *et al.* (1969) suggested that it improved depression, although Damasio (1970) found it caused depression. More recently, Choi *et al.* (2000) followed up a group of patients starting levodopa for up to 28 months and concluded that long-term levodopa had no impact on depression in Parkinson's disease. Klaassen *et al.* (1995) have

reviewed the use of antidepressant medication. Several studies were found that used selegiline as an antidepressant, with mixed results. More recently, Lemke *et al.* (2005) and Reichmann *et al.* (2003) have demonstrated the antidepressant effects of pramipexole in parkinsonian patients.

Tricyclic antidepressants are the most commonly studied drugs, although the methodologies used have been heavily criticised. The Parkinson's disease population is particularly susceptible to many of the adverse effects of tricyclics, such as orthostatic hypotension and confusion secondary to their anticholinergic effects. Additionally, absorption of levodopa can be impaired.

Since Klaassen *et al.*'s review there have been a number of studies investigating the efficacy of selective serotonin reuptake inhibitors (SSRIs) (Ghazi-Noori *et al.* 2003). With fewer noradrenergic and anticholinergic side effects, SSRIs would appear to be better tolerated in a parkinsonian population. Several open-label studies have been reported (Hauser & Zesiewicz 1997; Meara & Hobson 1998; Ceravolo *et al.* 2000; Rampello *et al.* 2002). Dell'Agnello *et al.* (2001) have concluded that SSRIs do not worsen the motor symptoms of the disease despite several case reports that they can produce parkinsonian signs in healthy individuals (Meltzer *et al.* 1979; Bouchard *et al.* 1989). Wermuth *et al.* (1998) have performed the only randomised controlled trial to date and found no benefit from citalopram over placebo.

ECT is not contraindicated, and may result in pronounced motor benefit while alleviating the affective disorder (Lebensohn & Jenkins 1975; Douyon *et al.* 1989). There are numerous reports of ECT successfully treating depression in Parkinson's disease, although no controlled trials have been performed (see Kennedy *et al.* 2003 for a comprehensive review). A large proportion of patients experienced confusion or delirium afterwards, somewhat limiting the usefulness of this approach in all but the most resistant cases.

Psychological therapies for depression, such as cognitive behavioural therapy, are safe, effective and popular with patients and now widely used in the general population. However, almost no work has been done in parkinsonian patients. In a small study Dreisig *et al.* (1999) suggested that younger patients may benefit. Crews and Harrison (1995) have suggested possible adaptations to cognitive behavioural therapy for use in an elderly population. Secker and Brown (2005) suggest that cognitive behavioural therapy may be helpful in the management of carer distress.

Relative to depression, anxiety in Parkinson's disease has received very little attention (Marsh 2000). Anxiety symptoms are common: Marinus *et al.* (2002) used the Hospital Anxiety and Depression Scale (Zigmond & Snaith 1983) to show that 20% of patients had 'probable' anxiety and 29% had 'possible' anxiety. Often the anxiety symptoms are part of a broader depressive syndrome but this is not always the case (Henderson *et al.* 1992). Like depression, anxiety symptoms often precede the onset of motor symptoms (Hender-

son *et al.* 1992). Shiba *et al.* (2000) found that a history of anxiety disorders was more common in patients with Parkinson's disease than in controls (odds ratio 2.2), however far back the history was examined. In a large prospective study of male health-care professionals, Weisskopf *et al.* (2003) identified anxiety as a predictor of subsequent Parkinson's disease even when caffeine intake, smoking and anxiolytic medication had been controlled for. Menza *et al.* (1999) associated anxiety in Parkinson's disease with a functional polymorphism on the serotonin transporter gene. There is no evidence for the treatment of anxiety in Parkinson's disease: SSRIs are probably the best option and benzodiazepines should be used with great caution. Intriguingly, several reports have shown an improvement in anxiety symptoms following pallidal surgery (Troster *et al.* 1997; Scott *et al.* 1998; Junque *et al.* 1999; Higginson *et al.* 2001).

Personality changes

Increasing disability may understandably lead to irritability, as in any disease which results in restriction of activities and dependence on others. Egocentricity, querulousness and an exacting attitude towards those around have often been stressed, likewise a change towards suspiciousness or even frank paranoia. However, the prevalence of such changes is hard to assess. Obsessional traits in the premorbid personality may become exaggerated, and hypochondriasis can be marked. In contrast, euphoria appears to be distinctly rare and when present is probably closely tied to intellectual deterioration.

There does not appear to be any form of personality change specific for parkinsonism. The majority of the features outlined above are generally held to be accountable in terms of individual vulnerability and the psychological and social stresses which operate on the disabled person.

Psychoses

Psychosis in untreated Parkinson's disease is rare. When it does occur it is usually affective in nature. This is almost always depressive, Mindham (1970) finding no examples of mania in a retrospective survey of 89 patients admitted to a psychiatric hospital. Only two had schizophrenic illnesses, one with postencephalitic and one with arteriosclerotic parkinsonism. Davison and Bagley (1969) note that reports of schizophrenia-like psychoses in association with idiopathic Parkinson's disease are rare and review the occasional examples in the literature. Crow *et al.* (1976) report four further cases, two with postencephalitic and two with idiopathic parkinsonism. Today, psychotic symptoms in parkinsonian patients are most often due to medication, as discussed below.

Psychiatric complications of anticholinergic drugs

Anticholinergic drugs may produce an acute organic reaction that sometimes leads to diagnostic difficulty. Porteous

and Ross (1956) reported mental disturbance in 20% of patients treated with trihexyphenidyl (Artane), sometimes in response to small doses. Symptoms included confusion, excitement, agitation, paranoid delusions, hallucinations and suicidal intentions, all rapidly disappearing when the drug was withdrawn. The disorder was usually evident soon after starting the drug, for example Minagar *et al.* (1999) report a case that followed the single administration of a scopolamine patch for travel sickness. Others could sometimes be gradual in evolution, with a risk that the relationship to treatment would be overlooked. Stephens (1967) and Crawshaw and Mullen (1984) have reported misuse of trihexyphenidyl in high dosage for its hallucinogenic properties, sometimes with outbursts of severe pathological excitement. Adverse reactions in parkinsonian patients are mostly seen in the elderly. They are also especially common when anticholinergics are added to levodopa, even in low dosage (De Smet *et al.* 1982). Anticholinergic psychoses often occur in the context of a delirium, which distinguishes them from other forms of psychosis seen in parkinsonian patients. Hallucinations are more often multimodal and are more likely to be perceived as threatening (Saint-Cyr *et al.* 1993).

Amantadine in high dosage may likewise provoke acute organic reactions where hallucinations occur within a delirium (Schwab *et al.* 1969; Dallos *et al.* 1970; Postma & Van Tilburg 1975; Timberlake & Vance 1978).

Psychiatric aspects of treatment with levodopa and dopamine agonists

Prior to the advent of dopaminergic medication, psychosis in parkinsonian patients whilst observed was rare. Mjones (1949) could find no support for the idea of a special paralysis agitans psychosis and many of the earlier examples, with florid delusions and auditory and visual hallucinations, were no doubt the product of overmedication with hyoscine, atropine or other solanaceous drugs. Others probably did not have idiopathic disease; in Mindhams's retrospective study (1970) one psychotic patient had 'arteriosclerotic' Parkinson's disease whilst the other was postencephalitic. Reports of psychosis increased with the availability of levodopa (Cotzias 1969; Ceesia & Wanamaker 1972). In an early review, Goodwin (1971) noted that psychiatric symptoms were the third most common group of levodopa side effects after dyskinesias and gastrointestinal disturbance.

The definition of psychosis used has a substantial bearing on any estimate of prevalence. Some early reports used a broad definition of psychosis that included confusion and agitation; Sweet *et al.* (1976) found psychosis in 60% of their patients. Tighter definitions yield lower rates. In his review Cummings (1991) suggested a figure of 40%. In a thorough community-based survey using the NeuroPsychiatric Inventory, Aarsland *et al.* (1999a) found hallucinations in 27% and delusions in 16%. Fenelon *et al.* (2000) included

'minor' hallucinatory experiences that may be missed with standardised assessment tools. These include 'presence' hallucinations in which the patient has the sensation of another person in the room, often behind them, and 'passage' hallucinations where the experience is one of a person (or animal) passing briefly by on one side. If these experiences were included, 39.8% of their 216 patients had psychosis.

Visual hallucinations are the most common feature of psychoses emerging with treatment in Parkinson's disease. Typically they occur in a clear sensorium, thus distinguishing them from a delirium. They occur with eyes open, often in dim surroundings (Barnes *et al.* 2003), and more frequently in the afternoon or evening (Manford & Andermann 1998; Barnes *et al.* 2003). They are distinguished from illusions by their complexity and the vivid colours and detail with which they are reported. They are usually brief, lasting seconds or minutes (Barnes *et al.* 2003).

Hallucinations in other modalities are reported much less frequently. Auditory hallucinations occasionally occur in isolation (Moskovitz *et al.* 1978) or alongside visual hallucinations (Graham *et al.* 1997; Fenelon *et al.* 2000; Factor & Molho 2004; Paleacu *et al.* 2005). They are first- or second-person, non-distinct, like voices in a crowd, and not generally threatening. It is rare for a visual hallucination to be the source of any auditory hallucination (Inzelberg *et al.* 1998). Tactile (Fenelon *et al.* 2002; Paleacu *et al.* 2005), gustatory (Holroyd *et al.* 2001) and olfactory (Tousi & Frankel 2004) hallucinations have also been reported. Jimenez-Jimenez *et al.* (1997) reported synaesthetic hallucinations, whilst Factor and Molho (2004) reported a case of Cotard syndrome.

Delusions occur less frequently than hallucinations (Cummings 1992b). They are often persecutory (Naimark *et al.* 1996; Sanchez-Ramos *et al.* 1996). Capgras syndrome has been reported (Lipper 1976). Formal thought disorder is very rare indeed (Cummings 1992b; Fernandez *et al.* 1999). An unexpected increase in sexual drive was noted by several authors soon after the introduction of levodopa (Barbeau 1969; Jenkins & Groh 1970). On occasions this might take the form of paraphilias (Harvey 1988; Cummings 1991; Quinn 1996).

No particular feature of the disease has been shown to be associated with the emergence of psychosis (Friedman 1991). Aarsland *et al.* (1999a) found a trend towards a higher score on the NeuroPsychiatric Inventory in patients with predominantly left-sided disease, although Shergill *et al.* (1998) reported more right-sided disease in patients with psychotic symptoms. Several authors have noted that a number of their psychotic patients had a past psychiatric history of both affective and psychotic disorders (Mendis 1996; Sanchez-Ramos *et al.* 1996; Juncos 1999). Increased age and duration of illness are frequently reported to be risks for the development of psychosis in Parkinson's disease (Cummings 1988; Vieregge 1996; Parkinson Study Group 1999; Fenelon *et al.* 2000).

That reports of psychoses became more frequent after the introduction of levodopa has led to a perception that there is a direct relationship between the two, i.e. that these are drug-induced psychoses. Tobias and Merlis (1970) showed that levodopa aggravated the mental status of patients with schizophrenia and several early studies claimed that there was a dose-response relationship between levodopa and psychosis (Cotzias *et al.* 1971; Ryback & Schwab 1971). However, these claims have largely been refuted (Sanchez-Ramos *et al.* 1996; Graham *et al.* 1997; Klein *et al.* 1997; Aarsland *et al.* 1999a) and other evidence points to a more complex relationship between levodopa and psychosis. Most obviously, despite the high prevalence of psychosis, most patients tolerate levodopa for many years without becoming psychotic. Additionally, Goetz *et al.* (1998) gave intravenous levodopa to parkinsonian patients who had already experienced hallucinations and observed no worsening in symptoms.

Psychosis has also been reported to complicate treatment with dopamine agonists, including bromocriptine (Burton *et al.* 1985; Montastruc *et al.* 1989; Cummings 1991), lisuride (Vaamonde *et al.* 1991), pergolide (Jankovic 1985) and apomorphine (Frankel *et al.* 1990). Recent evidence shows that psychosis is two to three times more likely with dopamine agonists than with levodopa (Rinne *et al.* 1998; Parkinson Study Group 2000; Rascol *et al.* 2000); indeed psychiatric side effects are the most common reason for their discontinuation (Montastruc *et al.* 1993). Several authors claim that the psychoses seen with dopamine agonists are more florid and persistent than those seen with levodopa (Lieberman *et al.* 1985; Vaamonde *et al.* 1991). Again, however, a simple relationship is questioned: Turner *et al.* (1984) noted that few patients receiving dopamine agonists for other indications become psychotic.

Aarsland *et al.* (1999a) have reported that approximately one-quarter of parkinsonian patients have vivid dreams and recent research has focused on the association between sleep disturbance and psychosis. High rates of vivid and abnormal dreams are seen in patients who had hallucinations or delusions (Moskovitz *et al.* 1978; Pappert *et al.* 1999). A 'continuum hypothesis' has emerged, suggesting that vivid dreams can be followed by sleep fragmentation and then visual hallucinations emerge in a temporally predictable sequence (Moskovitz *et al.* 1978; de Maingreville *et al.* 2005). This has been questioned (Goetz 2005) and remains unproven. Schenck *et al.* (1987) first reported an association between Parkinson's disease and rapid eye movement (REM) sleep behaviour. Arnulf *et al.* (2002) found that 39% of patients had brief periods of REM sleep during the day. Many of these REM periods corresponded with periods when they complained of hallucinations. Nomura *et al.* (2003) repeated these findings and also discovered that hallucinating patients had higher proportions of stage 1 REM sleep. In contrast, Manni *et al.* (2002) studied hypnopompic

and hypnagogic hallucinations and found that they were embedded in non-REM sleep rather than REM sleep.

Visual hallucinations in Parkinson's disease have been associated with abnormal ocular or visual functioning. Double vision, reduced visual acuity, impaired colour vision, impaired spatial contrast discrimination and impaired facial recognition have all been associated with hallucinations (Diederich *et al.* 1998; Holroyd *et al.* 2001; Crevits 2003; Davidsdottir *et al.* 2005).

One of the strongest predictors of psychosis in Parkinson's disease is cognitive impairment (Aarsland *et al.* 1999a,b; Fenelon *et al.* 2000; Paleacu *et al.* 2005). Papapetropoulos *et al.* (2005) found that prolonged disease, greater disease severity and greater cognitive impairment were each independent predictors of hallucinations. Aarsland *et al.* (2001a) found psychosis with increasing frequency in patients with non-demented Parkinson's disease, demented Parkinson's disease and dementia with Lewy bodies. One conclusion might be that psychotic symptoms are related to the density of cortical Lewy bodies. Barnes *et al.* (2003) suggest that the association between cognitive impairment and hallucinations may represent a final common pathway of general degeneration in information processing, a marker of diffuse brain disease or a specific impairment in complex visuospatial functions.

There is evidence for the involvement of the dopamine, serotonin and acetylcholine neurotransmitter systems. Clearly, there is a role for the dopaminergic system, although the simple explanation of receptor hypersensitivity must be questioned. For example, Mellers *et al.* (1995) compared the growth hormone response of both psychotic and non-psychotic patients to apomorphine. No differences were found between the two groups, suggesting equal levels of dopamine sensitivity. Birkmayer *et al.* (1974) found lower levels of tryptophan in the brainstem and increased serotonin in the substantia nigra of psychotic patients. They suggested that hallucinations might arise from an imbalance of serotonin and dopamine. Visual hallucinations also occur with lysergic acid diethylamide (LSD), which acts at the 5HT₂ receptor (Sadzot *et al.* 1989). The association of cognitive impairment with hallucinations suggests a role for the cholinergic system. Reduced levels of cortical choline acetyltransferase have been found in psychotic patients (Perry *et al.* 1990; Choi *et al.* 2000), and Nakano and Hirano (1984) found atrophy of the nucleus basalis in both Lewy body disease and Alzheimer's disease.

Psychosis impacts on the quality of life of patients and their carers. Initially, many patients retain insight into the nature of their experiences. Graham *et al.* (1997) reported that 70% of their patients had retained insight. Aarsland *et al.* (1999a) found that in 1 week 10% of patients had hallucinations retaining insight, whereas 6% of patients had hallucinations with no insight. Later as the disease progresses, insight is often lost. With advancing disease the burden of

caring for the patient increases (Carter *et al.* 1998). Psychosis is the single greatest factor precipitating nursing home placement in parkinsonian patients (Goetz & Stebbins 1993; Aarsland *et al.* 2000). Goetz and Stebbins (1995) showed higher mortality in hallucinating patients, but a more recent study from the same group showed that prognosis has improved (Factor *et al.* 2003).

Dose reduction or drug withdrawal is the initial strategy in the management of psychosis in Parkinson's disease. Any recently added medications should be adjusted first. In patients on stable medication, anticholinergics, followed by dopamine agonists and then COMT inhibitors should be withdrawn if motor symptoms permit (Duncan & Taylor 1996; Fernandez 1999; Juncos 1999).

The introduction of atypical antipsychotic medication brought hope that effective drug treatment would be possible. This has only been partly fulfilled. There were initial positive studies of risperidone (Meco *et al.* 1994; Allen, R.L. *et al.* 1995; Koponen 1997) and olanzapine (Wolters *et al.* 1996; Beasley *et al.* 1997). However, Meco *et al.* (1997) followed up their initial group, finding marked deterioration in motor function, and Graham *et al.* (1998) and Aarsland *et al.* (1999c) have shown that few patients are able to tolerate the sedating effects of olanzapine. More recently, Breier *et al.* (2002) reported that two randomised controlled trials have failed to show a benefit of olanzapine over placebo. Quetiapine has so far been shown to be safe and effective (Fernandez *et al.* 1999; Juncos *et al.* 2004). However, some worsening of motor signs has been reported (Fernandez *et al.* 2000; Friedman & Factor 2000), more often in cognitively impaired patients (Reddy *et al.* 2002).

Perhaps the drug that has been shown to be most effective is clozapine. Despite an early randomised controlled trial showing disappointing results (Wolters *et al.* 1990), many positive studies have been published. The Parkinson Study Group (1999) and the French Clozapine Parkinson Study Group (1999) performed randomised controlled trials which showed that clozapine was safe and effective at doses very much smaller than those used in the treatment of schizophrenia. A follow-up study has shown this remains true after 2 years (Fernandez *et al.* 2004). Fernandez *et al.* (2005) and Pollak *et al.* (2004) both report high rates of psychotic relapse if clozapine is withdrawn. The drawback in using clozapine is the risk of agranulocytosis, necessitating frequent blood tests. There is a single case report of clozapine-induced aplastic anaemia in a psychotic parkinsonian patient (Ziegenbein *et al.* 2003).

An alternative approach is the use of anticholinesterase drugs developed for use in Alzheimer's disease. In a small case series performed by Bergman and Lerner (2002) it appeared safe and effective, although Cummings (2000) has observed worsening of parkinsonian motor signs in dementia with Lewy bodies. Reading *et al.* (2001) found rivastigmine to be effective in improving hallucinations, cognitive

function and carer distress. The drug was relatively well tolerated, although nausea was a dose-limiting side effect. ECT has also been shown to be effective (Hurwitz *et al.* 1988; Friedman & Gordon 1992). A novel and successful approach was reported by Factor *et al.* (1995a) who initially treated two patients with both clozapine and ECT and then used clozapine as maintenance therapy.

Premorbid personality and psychological precipitation of Parkinson's disease

As with certain other neurological diseases, there have been occasional suggestions that the premorbid personality of patients with Parkinson's disease has characteristic features. Closely associated is the proposition that psychological influences may be important in the development of the disorder. None of the observations in this area can be regarded as well founded, but neither can it be said that they have been decisively disproved.

Certain striking qualities in patients with Parkinson's disease have been stressed: their industriousness, rigid moralistic attitudes and habitual suppression of aggression prior to the appearance of the disease. Sands (1942) and Booth (1948) championed the view that persons of a particular psychological make-up were at special risk of developing the disorder. Sands (1942) described what he called the 'masked personality', finding a marked discrepancy between the outward appearance of coping and the turmoil within. Premorbid histories showed the patients to have been exemplary citizens, successful in their undertakings and externally calm, undemonstrative and stable. Close acquaintance, however, revealed a subjective state of tension that was suppressed and concealed from outsiders. With the development of parkinsonism a decompensation could often be observed, exposing the inner turmoil in the form of complaints, demands and self-centred behaviour. Sands suggested that the habitual suppression of emotion, doubtless involving intense physiological activity in many parts of the brain, may have led in some way to the degenerative changes responsible for the disease.

Booth (1948) developed such concepts further in a clinical study of 66 patients supplemented with Rorschach protocols. Some were postencephalitic and some 'senile degenerative' in origin. He concluded that the personality structure had been more decisive for the development of parkinsonism than the immediately obvious pathogenic mechanism; the latter had merely served to precipitate or actualise the disorder. Features stressed by Booth included a habitual impulse to action and a striving for success, independence and authority. Tension was prone to arise between this and the equally strong drive towards social conformity. But such tensions, like other emotions and impulses, were firmly suppressed. Regarding their success in life, he found this to be usually the result neither of great intelligence nor of unusual vitality, but attributable to aggressive perseverance and

instinctive social conformity. An externally virtuous and docile disposition concealed hostile and sadistic impulses of unusual strength.

Such a character structure would be vulnerable to frustration in a number of ways. In many examples the first clinical symptoms of parkinsonism were preceded by a situation that had imposed a serious handicap to the execution of self-willed strivings and activities – arthritis, exhaustion, economic losses or professional disappointments. In other patients psychological conflicts could be identified as precipitants. Booth saw the major symptoms of parkinsonism as reflecting the original personality and its conflicts, rigidity for example being the product of a balance between overcoming obstacles and submission to restrictive influences, and the parkinsonian posture being related to unconscious hostility. Psychotherapy, in conjunction with antiparkinsonian medication, was claimed to meet with success in alleviating the symptoms.

There has been little support for these ideas from more recent studies. Diller and Riklan (1956) attempted an objective assessment of personality and background in a large number of patients referred for stereotactic surgery, but found nothing that could be regarded as characteristic for Parkinson's disease. Smythies (1967) compared 40 consecutive patients referred for surgery with control groups on a questionnaire relating to childhood disturbance, premorbid neurotic symptoms and life adjustment. No excess of premorbid emotional disability could be discerned, and no unusual difficulties in life adjustment antedating the illness. However, Pollock and Hornabrook (1966) were impressed with the high proportion of teetotalers among their large unselected series of parkinsonian patients, and found that many lacked hobbies and showed narrow intellectual horizons. Poewe *et al.* (1990) compared groups of patients with Parkinson's disease and benign essential tremor with healthy controls, using Cattell's personality inventory and a structured interview. Both patient groups were significantly more likely to be introverted, rigid, pedantic and self-reproachful than the controls, confirming previous impressions of personality. However, the similarity between the parkinsonian and tremor patients suggested that such traits were merely the product of chronic disability.

More interesting findings have come from comparisons between pairs of monozygotic twins, one of whom had Parkinson's disease while the other did not (Duvoisin *et al.* 1981; Ward *et al.* 1984). The affected members tended to describe themselves as more nervous, quiet, serious and introspective, whereas their co-twins were more outgoing and light-hearted. Moreover, a group of traits showed significant differences before the onset of the Parkinson's disease: the affected twin was less commonly the leader, less aggressive, more self-controlled and less confident. These differences in personality sometimes dated well back into adolescence and early adult life. It seemed possible therefore that neuro-

chemical differences between the twins might have existed from early in their lives, or that there had been some error of fetal development in the member destined for the disease.

Twin studies have also been employed to detect risk factors for the illness. The only possible association that has emerged is that affected twins have smoked less often and less heavily than their co-twins (Ward *et al.* 1984; Bharucha *et al.* 1986), which is interesting in that animal studies have indicated a dopaminergic effect of smoking on the brain. Baron (1986) reviews the epidemiological evidence from many case-control studies which also suggest that smoking may be protective, though with occasional negative reports (Golbe *et al.* 1986). It is possible, however, that differences in smoking habits reflect no more than differences in personality.

Lack of motivation, or apathy, often seen simply as part of a depressive disorder, has now been studied in its own right. Marin (1996) defined apathy as a motivation in affect behaviour and cognition. This was operationalised by Starkstein *et al.* (1992b) as (i) diminished goal-directed behaviour, (ii) diminished goal-directed cognitions and (iii) diminished concomitants of goal-directed behaviour, which (iv) cause distress and (v) are not due to reduced level of consciousness or effects of medication. The prevalence of apathy in Parkinson's disease ranges from 17% (Aarsland *et al.* 1999b) to 42% (Starkstein *et al.* 1992b). Apathy is more common in Parkinson's disease than in control subjects with osteoarthritis matched for disability (Pluck & Brown 2002), suggesting that it may be part of the disease process itself. Levy *et al.* (1998) showed that apathy was a feature of all neurodegenerative diseases. In this study apathy was variably associated with depression in each condition, although many studies confirm that they can be seen as discrete conditions (Starkstein *et al.* 1992b; Aarsland *et al.* 1999b; Shulman 2000; Pluck & Brown 2002). Pluck and Brown (2002) showed that apathy was associated with cognitive impairment. Apathy responds poorly to antidepressants and is not alleviated by levodopa (Pluck & Brown 2002). Chatterjee and Fahn (2002) have reported a case that improved with methylphenidate, whilst Lieberman *et al.* (1997) have suggested that pramipexole can be effective. Ready *et al.* (2004) showed that almost half of their male sample of apathetic patients were testosterone deficient and Okun *et al.* (2002) have suggested testosterone as a treatment.

Dopamine is the 'reward' neurotransmitter and major drugs of addiction stimulate dopamine release in the ventral striatal reward circuit. Although there is functional underactivity of the dopamine system in Parkinson's disease, PET studies show that amphetamine can stimulate prefrontal dopamine release even in advanced disease. It is perhaps unsurprising then that a small subgroup of patients report significant non-motor responses to levodopa. Some patients report that levodopa boosts energy and productivity independently of its effects on the motor system (Priebe 1984) and euphoria can occur during medication peaks (Serrano-

Duenas 2002). Conversely, drug withdrawal can be associated with dysphoria, anhedonia, anxiety and irritability (Serrano-Duenas 2002; Funkiewiez *et al.* 2003).

Giovannoni *et al.* (2000) have suggested criteria for a dopamine dysregulation syndrome.

- 1 Levodopa-responsive Parkinson's disease.
- 2 Need for increased doses of dopaminergic drugs.
- 3 Pattern of pathological use: demands for excessive medication in the presence of dyskinesias, drug-seeking behaviour, unwillingness to reduce dose.
- 4 Impairment in occupational or social functioning.
- 5 Development of manic syndrome in relation to dopaminergic medication.
- 6 Development of withdrawal syndrome in relation to dopaminergic medication.
- 7 Disturbance lasts at least 6 months.

Pathological use of levodopa has been reported. Evans and Lees (2004) described how patients can become impatient for the next dose and start to make dose increases themselves, whilst Nausieda (1985) described hoarding behaviours and patients seeking clandestine supplies of levodopa. Merims *et al.* (2000) reported the case of a patient who became quadriplegic yet still demanded levodopa. The removal of the drug led to signs of withdrawal that rapidly abated when levodopa was reintroduced. Such behaviours are most commonly reported with levodopa, often short-acting dispersible drugs. Abuse of dopamine agonists does occur though rarely in isolation from levodopa (Lawrence *et al.* 2003). Houeto *et al.* (2002) have reported compulsive use of a subthalamic nucleus stimulator.

Hepatolenticular degeneration (Wilson's disease)

Hepatolenticular degeneration is a rare inherited disorder affecting both the liver and the central nervous system first described by Wilson in 1912. The disease occurs in approximately 1 in 40 000 and is inherited in an autosomal recessive fashion. Over 200 mutations have been identified in the responsible gene, which is located on the long arm of chromosome 13 (Ferenci 2004). The gene encodes a membrane-bound copper-binding protein (ATP7B) expressed primarily in the liver that is responsible for transporting copper into the secretory pathway for incorporation in apoceruloplasmin and excretion in bile (Bull *et al.* 1993; Yamaguchi *et al.* 1993). Impaired elimination leads to copper accumulation in many organs and tissues, which gives rise to the clinical features of the disease.

Clinical features

The onset is usually in childhood or adolescence, but may be delayed as late as the fifth decade of life. Approximately half of patients are symptomatic by the age of 15. The presenta-

tion may be with hepatic disorder, neurological disorder or both. In addition, as discussed below, a considerable proportion present initially with psychiatric disturbance. One-quarter of patients have involvement of more than one organ system at the time of presentation (El-Youssef 2003). Bearn (1957) estimated that some 40% of cases first show hepatic dysfunction, 40% neurological symptoms, and perhaps 20% psychiatric illness or behavioural disorder. There is a marked tendency for the liver disorder to be the first to appear when the onset is in childhood.

Hepatic involvement is almost invariable but may sometimes be found only on liver biopsy or at autopsy. Jaundice or hepatosplenomegaly can be the presenting features. Initial investigation may yield a hepatitic or cirrhotic picture. Fulminant presentations are described with severe liver failure ascites, ankle swelling or haematemesis from rupture of oesophageal varices.

The neurological disorder is confined to the motor system and takes the form of extrapyramidal disturbance with a characteristic accent on the facial and bulbar muscles (Harding 1993). There may be rigidity, tremor, athetoid writhing movements and abnormal dystonic postures of the limbs. In the early stages the disabilities may be transient and sensitive to emotional influences, leading to an erroneous impression of conversion hysteria. A flapping tremor may be seen at the wrists, or characteristic 'wing beating' at the shoulders when the arms are abducted and the elbows flexed. The facial expression is stiff and motionless, often with open mouth and a rigid silent smile. Bulbar symptoms take the form of spastic dysarthria and dysphagia.

Occasional patients develop epileptic seizures, usually of Jacksonian type. Denning *et al.* (1988) found that seizures were 10 times as frequent as in the general population. Hemiplegia is not uncommon. Periods of coma or semicoma may develop, persisting for several weeks but not necessarily heralding a fatal outcome.

Variations in the clinical picture depend to some extent on the age at presentation (Bearn 1957). In young subjects dystonia or spastic rigidity tend to dominate the picture and tremor may be slight. The course is then liable to be acute and rapidly progressive. In adults tremor predominates and rigidity may be unobtrusive, with a milder course and slower progression. A good deal of overlap occurs, however, and mixed pictures are common. In the earlier literature the term 'lenticular degeneration' was used for cases showing spasticity, rigidity and dystonia, and 'pseudosclerosis' for cases with marked tremor and dysarthria. The lenticular presentation is said to occur earlier, with the pseudosclerotic presentation more common in adulthood (El-Youssef 2003).

The Kayser-Fleischer ring is a diagnostic sign of great importance. It is situated at the margin of the cornea, is brown or greyish-green in colour, and is often evident to the naked eye although all patients should be examined with a slit-lamp. It consists of copper deposits in Descemet's mem-

brane in the limbic area of the cornea. Absence of a Kayser–Fleischer ring makes the diagnosis of Wilson’s disease improbable in the presence of neuropsychiatric symptoms, but it may be absent in purely hepatic forms of the disease. However, Kayser–Fleischer rings are not pathognomonic; they may also be seen in primary biliary cirrhosis and autoimmune hepatitis. Sunflower cataracts may also be seen in Wilson’s disease.

Computed tomography and magnetic resonance imaging (MRI) have been found to show a characteristic picture (Williams & Walshe 1981; Aisen *et al.* 1985). Ventricular dilatation, cortical atrophy and enlargement of the cisterns around the brainstem are common, and may be accompanied by typical hypodense areas in the basal ganglia on CT. This combination is considered to be specific for Wilson’s disease. The hypodense areas are most frequent in patients with neurological disability, but can also be seen in those presenting with hepatic disorder or even in presymptomatic cases. MRI characteristically shows symmetrical focal areas of increased signal, especially in the lenticular nuclei (i.e. putamen and globus pallidus) but also in the thalamus, caudate nuclei, dentate nuclei and brainstem (Aisen *et al.* 1985). Focal white matter lesions may be observed in addition to hypointense areas on T2-weighted imaging (King *et al.* 1996). T2-weighted scans may show the ‘face of the giant panda’ sign, consisting of high signal intensity in the tegmentum except for red nucleus, preservation of signal intensity of the lateral portion of the pars reticulata of the substantia nigra, and hypointensity of the superior colliculus (Hitoshi *et al.* 1991). Rescanning after treatment with chelating agents may show resolution of the changes. PET has shown diffusely reduced brain metabolism, with a particular accent on the lenticular nuclei (Hawkins *et al.* 1987). It is not known why copper has a predilection for accumulating in certain parts of the brain.

Other features include abnormalities of renal function. Azotaemia occurs in 20% of patients and glomerular filtration rate can be lowered by 10%. Copper excess may not be responsible for glomerular dysfunction but is clearly linked to tubular disease. Aminoaciduria is seen in a high proportion of cases. Electrolyte abnormalities may precipitate nephrocalcinosis. Degenerative changes around joints are commonly seen on radiographic examination, even in young persons, and fractures and fragmentations of the bones of the hands and wrists may be detected. Copper deposits in the synovium can cause an arthritis. Cardiomyopathy, heart failure and conduction abnormalities have been described. Episodes of haemolytic anaemia may occur, presumably due to sudden release of copper from the tissues.

Course and outcome

Remissions may be seen in the earlier stages, and even thereafter marked fluctuations in severity can occur. Ultimately,

however, severe crippling results from spasticity and dystonic contractions. Dysphagia is often profound, and intellectual deterioration is common in the later stages. The prognosis is worse the younger the age of onset. Formerly children rarely survived for more than 4 years, whereas adults might survive without severe disablement for 12 years or more. Death usually occurs from liver failure, rupture of oesophageal varices, inhalation or intercurrent infection. With treatment this gloomy outlook has been altered as described below.

Pathology

Smith (1976) describes the pathological findings as follows. The brain is usually normal externally, but on section the corpus striatum is found to be shrunken and brownish or brick-red in colour. The putamen often shows cavitation. Microscopically, neuronal loss is seen in the caudate and putamen, and the latter contains large numbers of astrocytic nuclei, many having a characteristic enlarged and vesicular appearance (‘Alzheimer nuclei’). In contrast, the globus pallidus often shows relatively little change. Pericapillary concretions that stain for copper may also be detected. Other abnormal elements include large phagocytic ‘Opalski’ cells, possibly derived from histiocytes.

The thalamus, subthalamic nuclei and brainstem nuclei may also show Alzheimer nuclei and Opalski cells. Phagocytes containing iron pigment are commonly found in the substantia nigra. Degeneration of the dentate nuclei and superior cerebellar peduncles has occasionally been observed.

Foci of degeneration are not uncommon in the cerebral cortex, especially in the frontal lobes. Diffuse loss of neurones and fibres may occur, or status spongiosus involving both the cortex and the white centres of the convolutions. Astrocytic and oligodendrocytic proliferation may be seen.

The liver may be enlarged in the early stages but is usually smaller than normal at autopsy. It is coarsely cirrhotic, varying in colour from yellow to brown or brick-red depending on the relative amounts of copper storage, fatty degeneration and bile staining. Microscopically, the picture is of multilobular cirrhosis. The spleen is usually enlarged.

Biochemical abnormalities

The liver and brain contain a marked excess of copper, the basal ganglia being particularly heavily affected. The Kayser–Fleischer ring in the cornea is due to deposition of copper there, and levels may be raised in the kidneys and other tissues. The total serum copper is usually low and the excretion of copper in the urine is high ($>100\mu\text{g}$ in 24 hours).

More than 75% of patients have abnormally low caeruloplasmin. Caeruloplasmin is a globulin synthesised in the liver; 90% of serum copper is normally bound to caerulo-

plasmin, the remainder being loosely attached to serum albumin. This free copper is the toxic pool, probably representing the part in transition to other body regions, and it is raised in the disease. While important as a screening test, low values of caeruloplasmin are not invariable, some 5% of patients having normal levels and 10–20% of heterozygotes showing a deficiency (Starosta-Rubinstein 1995). Levels may also be reduced in protein-deficiency states and in the presence of liver disease. When the index of suspicion is high and caeruloplasmin is normal, a radioactive ^{64}Cu incorporation test can be valuable, revealing a lack of uptake of orally administered copper into newly synthesised caeruloplasmin. Definitive diagnosis can depend on liver biopsy, which reveals elevated copper levels and the histological changes of nodular cirrhosis.

With the advent of effective treatment, special attention must be directed towards the detection of asymptomatic but vulnerable individuals in the families of patients so that prophylactic treatment can be commenced. Once the disease has been diagnosed all siblings of the patient should be examined: 25% will be at risk and 50% will be heterozygote carriers. Discovery of a low caeruloplasmin should then lead to liver biopsy, which in the heterozygote may show a mild increase in liver copper, though not in the range of Wilson's disease, while liver histology is normal (Harding 1993).

Treatment

The aim of treatment is to eliminate excessive copper from the body and prevent its reaccumulation. Treatment must begin as soon as the diagnosis is made and continue for life. Dimercaprol (BAL) was the first chelating agent to be tried (Denny-Brown & Porter 1951). Results were encouraging but the injections were painful and liable to lead to toxic reactions. Penicillamine was the treatment of choice for many years. However, acute sensitivity reactions were common, sometimes ameliorated by steroids. Moreover, 50% of those presenting neurologically got worse, and half of these did not recover. Late side effects included skin changes, renal damage, systemic lupus erythematosus, myasthenia gravis, optic neuritis, bone marrow suppression and loss of the sense of taste. Low-copper diets no longer have a place in the management of the disease.

Alternatives to penicillamine have been developed. Trientine is considered by many to be the drug of choice as it has a lower incidence of adverse effects than penicillamine. Its exact mechanism of action is unknown. Sideroblastic anaemia is the major side effect. Tetrathiomolybdate, although yet to be licensed, shows considerable promise and is well tolerated. Brewer (2000a) suggests tetrathiomolybdate as the initial chelating agent for those presenting with neurological or psychiatric presentations. It complexes copper with food protein and prevents copper absorption. Zinc is the treatment of choice for lifelong maintenance. It

induces metallothionein in intestinal cells, which then prevents copper absorption, particularly that present in saliva and gastric secretion that would normally be reabsorbed. Zinc is essentially non-toxic, although 10% of patients experience gastric discomfort (Brewer 2000a).

Most patients make an excellent recovery from both hepatic and neurological disorder, although a small proportion fail to respond to medication and follow a steady downhill course to death over several weeks or months (Walshe 1986). Neurological improvement is often more rewarding than hepatic improvement given that almost all patients have a degree of cirrhosis at presentation. However, all aspects of the picture can respond. Tremor, rigidity, dystonia, dysarthria and dysphagia may all gradually resolve and some patients become entirely symptom-free. In general, improvement is more complete the earlier treatment has been commenced. Dramatic results have been reported from states of hopeless incapacity to relative independence, though such cannot always be achieved. Psychiatric symptoms have been found to improve as well, some more impressively than others. This is discussed in the next section.

Occasional patients will warrant liver transplantation, which effectively treats the Wilson's disease as well as the liver failure, restoring copper excretion to normal. Polson *et al.* (1987) have reported its success in reversing severe neurological manifestations, this occurring with unusual rapidity in one of their patients.

A man of 30 had a 14-month history of hepatic and neurological impairment. Despite treatment with penicillamine he developed increasing dysarthria, dysphagia, akinesia and rigidity of the limbs, requiring continuous nursing care. After transplantation liver function became virtually normal from 4 weeks onwards, and neurological recovery began 2–3 months later. By 8 months postoperatively no neurological signs were detectable.

Psychiatric manifestations of Wilson's disease

Psychiatric symptoms can form a prominent part of the clinical picture along with the neurological defects. On this account it is not uncommon for patients to present to psychiatrists before their disease is diagnosed, with a risk that treatment will be dangerously delayed. Denning and Berrios (1989a) recommend that serum caeruloplasmin should be measured in all psychiatric patients who show personality change, especially towards disinhibited, bizarre or reckless behaviour, in those who show neurological signs not accounted for by medication, and in patients with unexplained hepatic disease. Brewer (2000b) believes that all new

behavioural abnormalities in patients under 40 should lead to screening for Wilson's disease. Dysarthria and other bulbar symptoms will be a strong indication for investigation in patients below middle age, likewise deterioration in school or work performance in children or young adults. The following case illustrates the diagnostic difficulties that can arise.

A 17-year-old girl developed emotional lability, nervousness, difficulty with handwriting and deterioration in school performance. She was at first thought to be suffering from adolescent adjustment problems. Chlorpromazine was prescribed, leading to increasing tremor, and she became withdrawn. Abnormal liver function tests were noted, likewise mild extrapyramidal dysfunction, but both were ascribed to the drug. She was later hospitalised with a diagnosis of schizoaffective disorder. Finally, she was noted to show excessive drooling, a mask-like face, dysphagia, choreoathetoid movements, dystonia, spasticity, splenomegaly and Kayser–Fleischer rings. A diagnosis of Wilson's disease was confirmed 22 months after the first manifestations. Two years of treatment with penicillamine left her still dysphonic and with severe motor disability (Cartwright 1978).

Wilson (1912) stressed the prominence of psychiatric symptoms in his initial description and believed them to be a fundamental part of the clinical picture. He noted psychotic and hysterical manifestations, later adding affective change and disordered behaviour (Wilson 1940). Impairment of mental function seemed often to be more apparent than real, being to a large extent suggested by the patient's appearance and dysarthria. These various aspects have been reiterated in subsequent case reports and small series.

A more comprehensive picture emerges from a series of publications on the large number of patients referred to Dr John Walshe at Cambridge, this representing the largest series available in the UK (Denning & Berrios 1989a,b, 1990). Akil and Brewer (1995) have described a large series of patients from the USA. The careful documentation employed and the application of operationally defined criteria for the assessment of psychiatric disorder increase the validity of the findings, even though matters of special selection cannot be excluded. The principal conclusions are that personality change and 'incongruous behaviour' are undoubtedly common in Wilson's disease, while psychotic phenomena are rare. Irritability, aggression and depression appear to be frequent, likewise cognitive impairment of mild degree. Many of these psychiatric features appear to have an organic cerebral basis.

Denning and Berrios (1989a) first assessed 195 cases by retrospective case note review. Half were rated as showing some psychiatric disturbance at index admission and 20% had seen a psychiatrist before the disease had been diagnosed. Reasons for referral included deterioration in school or work performance, outbursts of abnormal behaviour and strange disorders of movement.

Personality change, in terms of alterations in lifestyle, relationships or behaviour, was judged as present or possible in one-quarter of patients. A similar proportion showed incongruous behaviour by way of disinhibition, bizarre or reckless behaviour, often leading to forensic problems. Evidence of such behavioural abnormality was significantly associated with high scores on ratings of neurological symptomatology, especially dysarthria. Irritability emerged in 18% and showed similar associations, and aggression was noted in 14%. Cognitive impairment was present or suspected in almost one-quarter, being generally mild, and depression in 21%. Depression showed associations with long duration of admission and the presence of family problems but little relationship to neurological symptoms.

In contrast, delusions and hallucinations occurred in less than 2% of patients, casting doubt on any significant relationship between psychotic illness and Wilson's disease. Disorientation was relatively rare at 7% and closely associated with liver failure.

A more intensive prospective study was made of 31 consecutive attenders at the clinic (Denning & Berrios 1989b). These ranged in severity from patients who had never been symptomatic to patients who were mute and bedridden. More than half were rated as abnormal on the Personality Assessment Schedule, the main factor on factor analysis reflecting traits such as impulsiveness, irresponsibility and aggression. One-third were 'cases' as judged by scores on the General Health Questionnaire. No psychotic symptoms were observed. Only four patients scored below the threshold for cognitive impairment on the Mini Mental State Examination, and in general such impairment was not severe.

Disorders of personality and behaviour were again significantly related to the presence of neurological symptoms, especially dysarthria, bradykinesia and rigidity, strongly suggesting that they had an organic basis. Depressive symptoms were related to hepatic dysfunction. Cognitive impairment, being mild in this sample, showed less marked correlation with neurological disorder than might have been expected; it was evident, moreover, that some patients who seemed superficially to be impaired performed well on psychometric tests.

Finally, an attempt was made to assess the response of neurological and psychiatric symptoms to treatment by retrospective review of 129 patients over a mean period of 10 years (Denning & Berrios 1990). Most gains had occurred during the early years of treatment, with improvement in cognition and 'incongruous behaviour' being significant. In contrast, depression and irritability seemed not to improve. Aspects of neurological disability also decreased signifi-

cantly, both early and later during treatment, including tremor, rigidity and overall neurological scores. However, dysphagia appeared often to persist and dysarthria to have a poor prognosis.

Other studies also report a high prevalence of depression, 27% in the study by Oder *et al.* (1991). Recent work by Hesse *et al.* (2003) has shown reduced central serotonergic activity and reduction in activity of the presynaptic serotonin transporter, thus calling into question whether the psychiatric features of Wilson's disease are caused directly by copper deposition. Cognitive impairment has been reported by Akil and Brewer (1995) and Rathbun (1996). It is generally mild, although Portala *et al.* (2000) found a range of deficits including concentration problems and lack of appropriate emotion even in treated patients.

Although Denning reported positive response of symptoms to treatment with penicillamine, this drug can also produce adverse neuropsychiatric consequences including seizures and psychosis (McDonald & Lake 1995). This is possible even if the patient were previously psychiatrically asymptomatic (Glass *et al.* 1990). Early reports of the use of tetrathiomolybdate suggest that psychiatric symptoms respond well without adverse effects (Brewer 1995).

Progressive supranuclear palsy (Steele–Richardson–Olszewski syndrome)

Steele *et al.* (1964) described a group of patients with an unusual progressive neurological disorder that manifested as an akinetic–rigid syndrome with ocular and mental features. Outstanding signs include supranuclear paralysis of external ocular movements, particularly in the vertical plane and involving downward gaze. This is sometimes described as a 'Mona Lisa stare'. Dysarthria is common and can be heard as a slurred growl. Pseudobulbar palsy, dystonic rigidity of the trunk and neck, cognitive impairment and signs of pyramidal tract and cerebellar dysfunction may also be seen. A tendency to fall over backwards is characteristic. In the later stages the eyes are fixed centrally, and widespread rigidity reduces the patient to a helpless bedridden state. The estimated prevalence is 5–6 per 100 000 (Schrag *et al.* 1999; Nath *et al.* 2001). The onset is usually in the sixth decade, with death some 5–10 years later. Subsequent reports have confirmed the main features of the syndrome (Steele 1972; Maher & Lees 1986; de Bruin & Lees 1992). Treatment with levodopa may sometimes ameliorate the rigidity and ophthalmoplegia for a time, but treatment response is often disappointing.

The pathology shows cell loss, neurofibrillary tangles, gliosis and demyelination, particularly affecting the basal ganglia, brainstem and cerebellar nuclei. The tangles consist of hyperphosphorylated tau proteins. Under the electron microscope they appear as bundles of straight filaments and

do not show the paired helical structure seen in Alzheimer's disease. Tau is also found in glial inclusion bodies. The distribution of changes is remarkably constant and usually there is a surprising lack of cortical involvement. Steele *et al.* (1964) commented on the resemblance of the histological features to those of postencephalitic parkinsonism or the parkinsonism–dementia complex of Guam, although the distribution of changes is different. The aetiology is unknown. Degenerative or viral processes are suspected, but attempts at transmission to primates have been unsuccessful. Rojo *et al.* (1999) believe that familial cases may be more common than previously thought. H1 is one form of the tau gene. Many patients are H1/H1 homozygous, 89% in one study compared with 65% of controls. However, H1 does not seem to influence age of onset or disease severity (Litvan 2001). Tau exists as six different isoforms, three of which have three repeated microtubule-binding domains whereas the remaining three have four repeated microtubule-binding domains. The normal brain has roughly equal amounts of three- and four-repeat tau, whereas Flament *et al.* (1991) have shown that in progressive supranuclear palsy the brain has three to four times more four-repeat than three-repeat tau.

Diagnosis can be difficult and the presentation may be confused with stroke, idiopathic Parkinson's disease, multiple system atrophy and corticobasal degeneration. Litvan *et al.* (1996) have described the clinical diagnostic criteria. Other findings include reduced set-shifting ability and concentration and more apathy and disinhibition in progressive supranuclear palsy than in idiopathic Parkinson's disease (Soliveri *et al.* 2000; Aarsland *et al.* 2001b). Schrag *et al.* (2000) suggested a set of MRI criteria including an axial midbrain diameter of less than 17 mm, signal increase in the midbrain, atrophy or signal increase in the red nucleus, and signal increase in the globus pallidus. Sphincter electromyography can be used to distinguish progressive supranuclear palsy from idiopathic Parkinson's disease but not from multiple system atrophy.

Among the psychiatric manifestations cognitive impairment is very common, affecting over 80% of the patients in de Bruin and Lees' (1992) survey to some degree. Of the 67 patients, five had presented with symptoms leading to an initial diagnosis of Alzheimer's disease, though early aphasia, apraxia and agnosia were never observed. Personality change, abnormal behaviour, emotional lability, depression and social withdrawal were all common.

The most striking cognitive change is bradyphrenia, with slowing of response. Apathy is significantly more common than in idiopathic Parkinson's disease (Aarsland *et al.* 2001b). Judgement is often found to be impaired and abstracting ability may be poor. The question of memory impairment in the disease has been controversial, with differing reports in different series. Here the clearest evidence has come from

Litvan *et al.*'s (1989) comparison of 12 patients with matched healthy controls. This revealed significant deficits in learning, consolidation and retrieval, also abnormally rapid rates of forgetting. In contrast, 'information scanning', which requires the use of short-term memory processes, remained intact. Verbal fluency tests also showed definite impairment. Both Schrag *et al.* (2003) and Aarsland *et al.* (2001b) report that one-third of their patients complained of difficulties with memory and concentration.

The memory disorder may owe much to deafferentation of the subcortical-frontal projections, since the cortical neurones themselves are generally spared. D'Antona *et al.* (1985) and Brooks (1993) have shown marked prefrontal hypometabolism on PET in comparison with controls of equivalent age. These observations are relevant to the question of 'subcortical dementia' discussed below.

Ovsiew and Schneider (1993) have reported a patient with autopsy confirmation of the disease in whom a schizophrenic psychosis was a central feature and present from the earliest stages. Josephs and Dickson (2003) found that 18% of their patients had a history of psychosis. Schrag *et al.* (2003) reported findings on 27 patient; using the Quality of Life Assessment Schedule, 54% reported depression and 29% reported anxiety. Depression was strongly linked to overall quality of life. Aarsland *et al.* (2001b) assessed 61 patients with the NeuroPsychiatric Inventory. Very high levels of apathy and disinhibition were found; depression and anxiety were as common as in the controls with Parkinson's disease.

Subcortical dementia

While the disease itself is rare, certain observations made on the mental state of such patients by Albert *et al.* (1974) have provoked considerable interest. The pattern of cognitive impairment seen in progressive supranuclear palsy appears to have distinctive features that may reflect the relative confinement of pathology to subcortical structures. Albert *et al.* termed this picture 'subcortical dementia'. In this they made a valuable contribution, by underlining the fact that cognitive failure does not always imply cortical disease. The cortex depends for its functioning on inputs from the reticular activating systems and other subcortical structures, and when these fail the cortex, though intact, may cease to display its potential.

Albert *et al.* (1974) contrasted the behaviour pattern in patients with progressive supranuclear palsy with that seen in patients with cortical disease processes. Among five cases seen personally and 42 adequately described in the literature, several key features were evident in the mental state. Though described as 'forgetful' it could frequently be shown that the patient could produce the correct answer if given encouragement and an abnormal amount of time in which

to respond. Memory as such appeared not to be truly impaired, but rather the timing mechanism that enables the memory system to function at normal speed. Slowness of thought was similarly prominent; tasks requiring verbal manipulation or perceptual-motor skills were performed incorrectly under normal pressures, but adequately when time was extended. Thus, when the patient was allowed to proceed at his own pace, or when provided with structured situations to elicit responses that did not occur spontaneously, his intellect could prove to be surprisingly intact. Defects of higher cortical function such as dysphasia, agnosia or apraxia were strikingly absent, though calculation or ability to deal with abstract material was sometimes defective. Personality and mood changes fell into two categories: the larger group was indifferent, apathetic and depressed, while the smaller showed progressive irritability and/or euphoria. Brief outbursts of rage were common, and inappropriate forced laughing and crying were often in evidence.

A woman of 65 with the disease showed extrapyramidal rigidity, slowed speech and marked limitation of upward and downward gaze. Her cognitive state was described as follows.

She was alert, attentive and socially appropriate. Immediate recall of digits was seven forward and five backwards. Recent memory was deficient in an unusual way: her first answer to almost every question was 'I don't know'. However, if the examiner encouraged her by saying 'Sure you know; just take your time', she would correctly respond to 95% of the questions. The latency between question and response was often inordinately long, in some cases as long as 4.5 minutes (often taxing the patience of the examiner). Remote memory was intact.

Language functions were as follows: no paraphasias were heard; naming was excellent on confrontation for high and very low frequency words. Although she complained of having difficulty with words, she had no naming defect. She did, however, have a time-related word-finding defect: in 1 minute she was able to find only three words beginning with the letter 'b'. At 5 minutes she had listed 12; at 10 minutes 23; at 15 minutes 33. Tests of repetition, comprehension of spoken and written language, and reading aloud were normal, except for the slow reading rate.

For simple mental calculations her responses were quick and accurate. With more complex arithmetic problems, she was slow but correct. Her proverb interpretations were concrete and she had difficulty finding similarities in two similar objects (Albert *et al.* 1974).

A 58-year-old woman had dysarthria, a broad-based ataxic gait and striking impairment of upward and downward gaze. Evaluation of mental status revealed an awake, generally placid or apathetic woman who reacted in a seemingly angry manner to the examiner's attempts to question her. Despite her apparent anger, she could nonetheless be coaxed to cooperate. Digit span was six forward. Questions designed to test recent and remote memory led to the following situation: either she refused to answer or she answered incorrectly. However, when the examiner waited, either silently or with attempts to encourage her, for longer than normal waiting periods (even as long as 4–5 minutes for a single question) she then gave the correct answer to 70–80% of the questions. This indicated that her stock of knowledge was not impaired as one might otherwise have concluded. Rather, she was delayed in reaching into the stock for the correct answer. Tests of language and gestures revealed no aphasia or apraxia. No inattention or primary perceptual problems were seen. Proverb interpretations tended to be concrete. Her ability to find the categorical similarities between similar items was impaired. Her calculating ability was poor (Albert *et al.* 1974).

Attention was drawn to rather similar pictures in other diseases with subcortical pathology, and the authors tentatively proposed that the common mechanisms underlying them were those of impaired timing and activation. Impaired functioning of the reticular formation, or disconnection of the reticular-activating systems from thalamic and subthalamic nuclei, might be the cause of slowing of intellectual processes, even though the cortical systems for perceiving, storing and manipulating knowledge remained intact.

The situation in progressive supranuclear palsy, in which the cortex is known to be largely spared, is likely to exist in some other dementing processes also. Parkinson's disease with intellectual impairment is an obvious example; Huntington's chorea is another (see Chapter 9 under Huntington's disease). Normal-pressure hydrocephalus, Wilson's disease and the dementia associated with deep lacunar infarcts (see under Premorbid personality and psychological precipitation of Parkinson's disease, earlier) have also been viewed in this way (Benson 1982; Cummings 1982). It could conceivably be the case that some variants of the dementias of old age may have a subcortical rather than a cortical origin to the cognitive difficulties, or at least a prominent subcortical component in the aetiology of the clinical picture. An interesting possibility is that the 'normal' effects of old age on cognitive functioning may reflect subcortical rather than cortical ageing processes (Albert 1978).

That a subcortical dementia might be both clinically and pathologically distinct from the more classical understanding of dementia as a cortical disease has produced much

research and debate (Pillon *et al.* 1993; Darvesh & Freedman 1996). In subcortical dementia the disease occurs largely in the basal ganglia, cerebellum and brainstem nuclei (Darvesh & Freedman 1996). Cerebrovascular disease is a common cause as are a number of neurodegenerative conditions. Psychiatric features are common, particularly depression, apathy and personality change. Psychosis is a feature in many presentations. Features such as agnosias, dysphasias and dyspraxias are more indicative of cortical dementias such as Alzheimer's disease.

The idea that dementias are either subcortical or cortical has since been challenged (Turner *et al.* 2002) and it would seem more likely that a spectrum exists between the two. Cortical pathologies do sometimes occur in subclinical diseases, Alzheimer-type pathology in Parkinson's disease for example (Hughes *et al.* 1992), whilst subcortical neuronal loss is seen in Alzheimer's. Moreover, a clinical picture very similar to Alzheimer's disease may be produced by (subcortical) thalamic lesions (Kopelman 1991).

Corticobasal degeneration (cortical–basal ganglionic degeneration)

This rare disorder was first described by Rebeiz *et al.* in 1968. Further series of patients have been reported by Gibb *et al.* (1989) and Riley *et al.* (1990). The condition is reviewed by Watts *et al.* (1994). Corticobasal degeneration consists of degeneration in defined regions of the cerebral cortex coupled with marked pathology in the striatonigral system and other subcortical nuclei. The clinical presentation can resemble progressive supranuclear palsy (see beginning of previous section: Progressive supranuclear palsy), while the pathological changes share features in common with Pick's disease. A clinical hallmark is the asymmetry of the motor manifestations, such that one limb may become completely incapacitated before symptoms develop on the other side.

It presents usually in late middle or early old age, with akinesia, rigidity, limb apraxia and a combination of supranuclear gaze palsy, myoclonus, limb dystonia or cortical sensory loss. Postural instability may be marked. The myoclonus is induced by action, and is often markedly stimulus sensitive. Ataxia, chorea, blepharospasm and pyramidal tract signs may also be seen. Not infrequently the patient develops an 'alien limb', whereby the hand and arm feel 'foreign' to the patient and tend to wander involuntarily and uncontrollably. This feature is discussed by Sawle *et al.* (1991) who ascribe it to damage to the medial frontal cortex and supplementary motor area.

Cognitive disabilities may be notably mild or absent even when severe apraxia hampers the majority of voluntary activity. Other patients, however, develop marked parietal lobe deficits that manifest as dyscalculia, constructional apraxia or visuospatial impairment. Severe generalised dementia supervenes in perhaps one-third of cases. High

rates of depression are seen, especially in comparison to progressive supranuclear palsy (Litvan *et al.* 1998), but less apathy and disinhibition. Psychosis appears to be infrequent. Rarely, cases show marked frontal lobe dysfunction, including aggression and even Kluver–Bucy syndrome (Nasreddine *et al.* 1999; Stover & Watts 2001). Onset is typically in the seventh decade (Wenning 1998). Progressive incapacity leads to death after 4–10 years. Treatment with levodopa is often ineffective, though baclofen may help the rigidity and clonazepam may dampen the myoclonus (Thompson & Marsden 1992).

Pathological findings consist of cortical atrophy with cell loss and gliosis, mainly affecting the peri-rolandic frontal and parietal regions in contrast to the frontotemporal atrophy of Pick's disease. Subcortical regions are also markedly affected, especially the globus pallidus, putamen, substantia nigra and lateral thalamus. The subthalamic nucleus, red nucleus and locus caeruleus are also involved. Abnormal neurones show marked resistance to staining methods (achromasia) and a swollen appearance similar to the ballooning of Pick cells. However, classic Pick bodies are not present. Basophilic inclusions are seen, especially in the substantia nigra, also globose neurofibrillary tangles similar to those of progressive supranuclear palsy. The same elevated ratio of four-repeat to three-repeat tau observed in progressive supranuclear palsy is also seen in corticobasal degeneration. As in progressive supranuclear palsy, the H1 allele is very common, 93% in one study (Houlden *et al.* 2001). Lang (2003) suggests this implies that corticobasal degeneration and progressive supranuclear palsy share a common genetic predisposition, although he notes that pathological evidence currently points to them being discrete entities (Ishizawa & Dickson 2001; Dickson *et al.* 2002).

Computed tomography and MRI show ventricular enlargement and cortical atrophy, which may be asymmetrical in distribution. Brain imaging with PET has revealed distinctive features that mirror the pattern of pathological involvement (Eidelberg *et al.* 1991; Sawle *et al.* 1991). Cortical hypometabolism is evident in the superior temporal, inferior parietal, posterior frontal and occipital association cortices, with a markedly asymmetrical pattern that may be of value in differential diagnosis. ¹⁸F-fluorodopa uptake is reduced in the caudate and putamen, again in an asymmetrical manner.

Striatonigral degeneration (multiple system atrophy)

Adams *et al.* (1964) drew attention to this rare disorder, closely similar to Parkinson's disease in clinical manifestations but with a distinctive pathological basis. Affected patients show rigidity, akinesia, slowed movements and a flexed posture. At autopsy the striking features are extensive neuronal loss in the zona compacta of the substantia

nigra, but without Lewy bodies, and marked degenerative changes in the putamen and caudate nuclei.

One of Adams *et al.*'s four cases also showed olivopontocerebellar degeneration. Many cases have since been reported with this striking combination, prominent cerebellar ataxia then preceding the parkinsonian symptoms. Moreover, approximately half are handicapped by fainting due to postural hypotension, and other signs of autonomic failure may include impotence and sphincter and deglutition disturbances. Such patients show neuronal loss in the intermediolateral tract of the spinal cord and the dorsal vagal nuclei of the brainstem (Shy–Drager syndrome). Dementia may develop but is uncommon. Gosset *et al.* (1983) reviewed 35 cases with both striatonigral degeneration and olivopontocerebellar degeneration, ranging in age from 30 to 75, half of whom also showed progressive autonomic failure. They termed this combination 'progressive multi-system degeneration'. Several patients also showed pyramidal signs, slight muscle atrophy, intention myoclonus and upward gaze palsy.

Nowadays it is usual to group these various conditions together under the title of multiple system atrophy. The neuropathological picture has now been more completely described. Cell loss and gliosis are widespread throughout the brainstem, cerebellum, basal ganglia and central autonomic nervous system. The hallmark is the diffuse presence of cytoplasmic inclusions that are positive for both α -synuclein and tau (Lantos & Papp 1994; Wenning & Quinn 1997; Dickson *et al.* 1999).

The condition should be suspected when a parkinsonian syndrome coexists with ataxia, vertical gaze palsy, pyramidal signs and evidence of autonomic failure such as postural hypotension. Quinn (1989) considers that it is less rare than commonly supposed, perhaps accounting for up to 10% of patients with parkinsonism, whereas Schrag *et al.* (1999) have estimated the prevalence to be 4.4 per 100 000. The condition starts most commonly in the sixth decade (Wenning & Geser 2003) and is associated with a median time to death of 9 years (Wenning *et al.* 1994). Diagnosis can be difficult, especially as autonomic problems are often missed by both patient and clinician (Colosimo & Pezzella 2002), but consensus criteria now exist (Gilman *et al.* 1998, 1999). The response to levodopa can be variable (Albanese *et al.* 1995; Wenning *et al.* 1995). Although Colosimo *et al.* (1995) reported a response rate of 68%, Quinn and Wenning (1994) have shown that the response to levodopa declines within a few years. Wenning and Quinn (1997) reported high rates of dyskinesias. Dopamine agonists tend to be no more effective than levodopa. Lang (2003) reports disappointing results from stereotactic surgery.

Clinically, there are prominent parkinsonian features in about 80% whilst cerebellar features dominate in the remaining 20% (Gilman *et al.* 1998). Postural or rest tremors may be seen. Dysautonomia is central to both subtypes. This may

include postural hypotension (Mathias & Kimber 1999), which is related to loss of preganglionic sympathetic neurones in the inferomedial cell column (Oppenheimer 1980). Bladder dysfunction is very common and results from detrusor hyperreflexia and urethral sphincter weakness (Bonnet *et al.* 1997). This contrasts with the urinary problems seen in Parkinson's disease where incontinence, if seen, is a late sign (Wenning *et al.* 1999). Sexual dysfunction (Wenning *et al.* 1994), constipation (Stocchi *et al.* 2000) and respiratory dysfunction (Wenning *et al.* 1994) are further examples of autonomic difficulties.

Sleep disorders, such as daytime sleepiness, insomnia and REM sleep behaviour disorder, are very common (Wenning *et al.* 1994; Ghorayeb *et al.* 2005). These do not appear to be related to depression, which is also common (Pilo *et al.* 1996; Fetoni *et al.* 1999; Gill *et al.* 1999). Benrud-Larson *et al.* (2005) in a study of 99 patients found that 39% had moderate to severe depression. Depression and, more strongly, autonomic dysfunction contributed substantially to the reported very low levels of life satisfaction. Importantly in contrast to the other parkinsonian syndromes dementia is not a feature, although mild frontal impairment or emotional lability might be seen (Pillon *et al.* 1995; Marti *et al.* 2003).

The dystonias

The dystonias comprise a group of disorders in which sustained muscle spasms invade muscle groups, causing writhing or twisting movements or distorting the body and limbs into characteristic postures. The abnormal movements differ from tics or choreiform movements in being much slower and sustained, and in their tendency to involve the proximal and axial musculature. Dystonias represent the third most common movement disorder after Parkinson's disease and essential tremor (Butler 2002). Reviews of the classification of these disorders and changing conceptions about them are provided by Fahn *et al.* (1998), Cavalho (2002) and Nemeth (2002).

Almost any body part may be involved. Typically at the onset the dystonia occurs only during some specific motor act, affecting a restricted group of muscles (focal dystonia). It may remain localised, or spread to involve contiguous body parts (segmental dystonia) or virtually all of the body (generalised dystonia). Axial dystonia is a focal dystonia affecting the trunk. Hemidystonia affects one half of the body alone, and multifocal dystonia affects several discrete regions. The different syndromes that result are often specially labelled: torticollis in the neck, blepharospasm in the muscles around the eyes, and dystonia musculorum deformans when the disorder is generalised. Focal and segmental dystonias greatly outnumber other forms; in the large series of almost 1000 cases reported from the Dystonia Clinical Research Center in New York these accounted for some

three-quarters of cases, generalised dystonia occurring in less than one-fifth (Fahn *et al.* 1987).

All dystonic movements and postures are worsened by attempts to move. When the spasms are continuous they result in characteristic postures that are maintained except during sleep. When intermittent they cause repetitive, often rhythmic, jerks and spasms, for example in torticollis. The shorter the spasms, the more 'myoclonic' the dystonia. Some patients may show an additional component of tremor. This can produce diagnostic confusion, with dystonias being mistaken for chorea, tremor or myoclonus (Langlois *et al.* 2003).

Some dystonias are symptomatic of structural or metabolic brain disease, following in the wake of perinatal hypoxia or kernicterus (athetoid cerebral palsy) or accompanying Huntington's or Wilson's disease. The basal ganglia, with their high oxidative metabolism, are particularly sensitive to hypoxic damage (Trost 2003). The symptomatic dystonias tend to be asymmetrical or unilateral, and to show other evidence of brain damage by way of seizures, intellectual impairment or pyramidal tract damage. Other dystonias may be induced by drugs such as neuroleptics or levodopa. The range of possible causes is legion, as listed by Marsden and Quinn (1990). In the majority of cases, however, no cause is found and the condition is labelled as a primary or idiopathic dystonia. A pathological cause is identified in some 45% of patients with generalised or multifocal dystonia, but only in 10% of those with focal dystonia. In contrast, hemidystonia is due to a structural cause in over 80% of cases, for example a stroke, head injury or brain tumour. It is essential that Wilson's disease, though rare, is excluded in all patients with onset of dystonia below the age of 50.

Age affects the chances of identifying a cause; in Fahn *et al.*'s (1987) series, 40% of cases were symptomatic when onset was in childhood, 30% when onset was in adolescence and 13% when onset was over the age of 20. Age also has a marked though ill-understood effect on the likelihood of progression to generalised dystonia. This occurred in 60% of Fahn *et al.*'s patients with onset in childhood, in 25% with adolescent onset, but in only 3% of adult-onset cases. The legs are usually affected first in children, less commonly in adolescents, and very rarely in adults.

An interesting small group of patients has been reported by Burke *et al.* (1980) in whom persistent dystonia developed after a considerable delay of 1–14 years following static cerebral insults such as anoxia, trauma or infarction. In the trauma and infarction cases, the body part affected corresponded to the site of the cerebral damage. Schott (1985) has drawn attention to patients who developed segmental dystonias in the wake of quite mild peripheral injuries such as falls, twisting the back or straining the arm or thumb, the movement disorder developing as the symptoms from the injury subsided. The site of the dystonia corresponded closely to that of the initial injury. Such rare examples contribute to the mystery surrounding the genesis of this group of conditions. Dystonias are the most common movement

disorders after severe head injury. The mean latency is nearly 2 years. The physiological basis of dystonia post head injury remains unclear, as it may occur when damage is apparently confined to cortical structures and not the basal ganglia (Trost 2003).

The dystonias are of importance to psychiatrists on many counts. Both acute and chronic forms can emerge as side effects of neuroleptic treatment, the latter providing considerable problems of management (see Acute dystonia, under Drug-induced disorders/Clinical pictures, earlier). They are also of interest in that they are markedly 'psychosensitive', being readily aggravated by intercurrent stresses and tensions (Fish *et al.* 1991). This can be so marked that at least in the earlier stages a psychogenic disorder is suspected, this being reinforced when psychological treatment leads to amelioration. Diagnostic mistakes can also arise from the bizarre nature of the movement disorder and the strange postures induced, leading to an impression of simulation, hysteria or catatonic posturing. Strange paradoxes can add to the confusion, as when the patient can run, dance or mount stairs normally while walking provokes considerable difficulty. Some patients can even walk backwards when walking forwards is a problem. Strange tricks or manoeuvres, such as the *geste antagoniste*, may be discovered by the patient to control the movement disorder. Difficulties with diagnosis are increased by the absence of abnormalities on formal neurological examination and investigation in the idiopathic dystonias, where diagnosis depends essentially on familiarity with the clinical pictures produced.

Not surprisingly, in view of the above, differing opinions have been held about the causation of dystonia from time to time. Many examples, and particularly the focal forms, were long considered to be psychogenic in origin, for example torticollis and blepharospasm. However, evidence now increasingly favours the view that both focal and generalised dystonias form part of a spectrum, founded in some subtle disturbance of brain biochemistry and physiology. One model focuses on the role of the basal ganglia in regulating motor activity, suggesting that there is functional impairment in output from the globus pallidus interna and the substantia nigra pars reticulata. This reduced activity leads to disinhibition of the thalamus and the motor cortex, producing abnormal movements (Berardelli *et al.* 1998; Vitek 2002). Vitek (2002) further suggests that dystonias arise from alterations in the rate, pattern, somatosensory responsiveness and synchronisation of neural activity in the pallido-thalamo-cortical circuits. The resurgence of such a view has depended on a number of factors: the demonstration of relationships between the different forms, observation of transitions from one form to another, the similarities in clinical picture between symptomatic and idiopathic cases, and not least the provocation of classic examples by a range of pharmacological agents. Moreover, careful control comparisons have increasingly failed to confirm an excess of personality

abnormalities or other psychopathology among the persons affected.

Genetic studies have pointed to an inherited vulnerability to idiopathic dystonia and a common origin for the different subvarieties. Fletcher *et al.* (1990) surveyed 100 British families containing 107 members with generalised, segmental or multifocal dystonia (53 generalised dystonia, 46 segmental, 7 multifocal and 1 hemidystonia). Of the index cases 58 had affected relatives. Altogether 79 secondary cases were discovered, almost half being unaware of their problem (generalised dystonia in 15 cases, segmental in 25, focal in 27, multifocal in 6 and tremor in 6). It was concluded that 85% of the cases were caused by an autosomal dominant gene or genes, with approximately 40% penetrance and highly variable expression. About 14% of singleton cases possibly represented fresh mutations. The estimated risk for siblings or children in familial cases was 21%, and the risk in sporadic cases 8–14%. There was no evidence of increased parental consanguinity. Nemeth (2002) and Cavalho (2002) review the current evidence regarding the genetics of dystonia. At least 10 dystonia genes have now been identified.

A genetic contribution to adult-onset focal dystonia is less clearly established but also seems probable. Waddy *et al.* (1991) examined the relatives of 40 patients with torticollis and orofacial dystonias. Ten of them had relatives with some form of dystonia, segregation analysis again suggesting the presence of an autosomal dominant gene or genes with reduced penetrance.

In a small proportion of cases it is nonetheless still accepted, even by experienced observers, that the dystonia is primarily psychogenic in origin. And of course in many patients there will be a strong interaction between organic predisposition and the modulating influence of emotional and environmental factors.

Dystonia musculorum deformans (generalised torsion dystonia)

Generalised torsion dystonia leads to severe and progressive crippling. A genetic basis is apparent in many cases. It must be distinguished from the symptomatic torsion dystonia that may follow severe perinatal anoxia or kernicterus; a similar picture may also be the presenting feature in Wilson's disease and was occasionally encountered after encephalitis lethargica. Within families who inherit the major disease other members may show formes frustes of the disorder: abnormalities of gait, abnormal arm postures, minor speech defects, or static postural abnormalities such as pes equinovarus or kyphoscoliosis.

Ozelius *et al.* (1997) reported the discovery of the gene *DYT1* on the long arm of chromosome 9, inherited in autosomal dominant fashion with partial penetrance, which is responsible for a form of early-onset dystonia. This form of dystonia has become a model for understanding the disease. The gene produces a mutant form of the protein torsin A, whose precise role awaits clarification. However, it is notable that post-mortem studies have revealed an imbalance of

dopamine signalling in the striatum of brains with genetically confirmed DYT1 dystonia (Augood *et al.* 2002). Pathological studies have occasionally reported abnormal findings in the basal ganglia, substantia nigra and elsewhere, but these are regarded as non-specific or even artefactual. However, the evidence points to involvement of the basal ganglia, both by analogy with examples that are symptomatic of known brain lesions and the response that may be observed to stereotactic surgery.

Clinical features

The symptoms usually commence in childhood or early adolescence. The first symptom is commonly a disturbance of gait, with plantar flexion, inversion and adduction of the foot when walking. At first the picture is sometimes bizarre with respect to the precise functions affected, as already mentioned. More rarely the initial disturbance may appear in the upper limbs with abnormal postures or actions. A characteristic dystonic posture consists of extension and hyperpronation of the arms, with flexion of the wrist and extension of the fingers. Occasionally the onset is with involvement of the trunk or with torticollis.

In the early stages the motor abnormalities may become apparent only when activity is attempted and nothing unusual can be found on examination at rest. Remissions lasting for several months at a time may occur, all adding to the erroneous impression that the disorder is psychogenic in origin. Indeed, a hysterical disturbance is not infrequently diagnosed initially, particularly when there are coexistent emotional problems or adverse environmental factors. Thus patients are occasionally encountered who have undergone years of psychotherapy for 'hysterical spasms' before progression of the disorder reveals the true state of affairs. The mistake is easily made in view of the rarity of the disorder and the bizarre nature of the symptoms. Other objective signs of a cerebral lesion are absent, with normal tendon reflexes and unimpaired intelligence. Moreover, the dystonic postures that can occur in conversion hysteria are sometimes indistinguishable from the transient early disturbances of dystonia musculorum deformans.

Later, the muscle spasms occur even when the body is relaxed, producing irregular spontaneous movements or fixed dystonic postures. Muscle groups may hypertrophy. The movements cease during sleep but plague the patient continually while awake. Other parts of the body come to be affected, usually with symmetrical involvement of all four limbs, the trunk and the neck. The proximal muscles tend to be affected more than the distal, and a rotatory element in the axial musculature is typical. The trunk is forced into marked lordosis or scoliosis, and fixed contractures of the limbs lead eventually to severe crippling and permanent deformity. Speech, swallowing and breathing may ultimately be affected. Tendon reflexes become difficult to obtain or may be exaggerated, but the plantar responses

remain down-going. There are no abnormalities of sensation.

Rapid progress and widespread involvement is usual when the onset is in childhood or adolescence. Maximum disability is usually reached within 5–10 years, after which the disease tends to arrest or sometimes may even improve very slightly. In about 5% of patients spontaneous remission occurs, usually lasting for only weeks or months but very occasionally being permanent (Harding 1993).

An important subgroup that must not be overlooked comprises patients with dopa-responsive dystonia or Segawa's disease (Nygaard *et al.* 1988, 1991). This accounts for an estimated 5–10% of patients with onset in childhood or adolescence. The gene responsible for this has been termed *DYT5*. It is found on the long arm of chromosome 14 and inherited in autosomal dominant fashion. The onset is typically with a curious abnormality of gait, for example walking on the toes with a wide base, progressing thereafter to the axial muscles producing lordosis and scoliosis. Parkinsonian features are prone to develop, with bradykinesia, rigidity and tremor, and spasticity with pyramidal signs may be present. Diurnal fluctuations and improvement after sleep have been emphasised, but probably do not discriminate the group from other dystonias. Worsening after exertion is characteristic. In Nygaard *et al.*'s review of 86 cases, 36 were sporadic and the rest had more than one family member affected.

The dramatic response to levodopa sets the group apart. Small doses give immediate benefit, with a return to normal or near normal after several days or months. Minor gait abnormalities may persist, but full functional capacity is usually regained. Doses as small as 100 mg have proved effective, though the average is in the range of 500–1000 mg.

Dyskinesias have not emerged as a problem with long-continued therapy. Patients have responded after remaining untreated for 25–45 years, and the benefit has been sustained in follow-ups of 10–20 years.

Treatment

Treatment of generalised torsion dystonia is often disappointing in the present state of knowledge, but in favourable cases drugs can bring substantial benefit. It is essential that all children and adolescents should have a 3-month trial of levodopa to see if they have the dopa-responsive form, particularly if the dystonia has started in the legs. If this fails the next drug to try is an anticholinergic, which helps about half of cases, sometimes very considerably (Burke *et al.* 1986; Greene *et al.* 1988). A start must be made very gradually, building up to high dosage over several months in order to avoid side effects. In children doses of up to 120 mg daily may prove to be well tolerated. Other drugs that may help if trihexyphenidyl fails include diazepam, clonazepam, baclofen, carbamazepine, tetrabenazine, or neuroleptics such as phenothiazines, haloperidol or pimozide. A combination which can be helpful in very severe dystonia is low-

dosage tetrabenazine with pimozide and trihexyphenidyl (Marsden & Quinn 1990). Care needs to be taken with phenothiazines, which may worsen the dystonia or cause tardive dyskinesia (Adler & Kumar 2000). Stereotactic brain surgery, including the use of deep brain stimulators, has shown positive effects but the optimum site is unclear. Unilateral thalamotomy may be helpful although bilateral procedures can be associated with dysphagia. There are a number of reports suggesting a positive outcome from bilateral pallidotomy (Lozano *et al.* 1997; Lai *et al.* 1999; Vitek 2002). Pallidal stimulation is an alternative (Coubes *et al.* 2000; Volkmann & Benecke 2002).

Increase rates of major depressive disorder are seen in DYT1 dystonia (Pittcock *et al.* 2000). In one study patients and neurologically asymptomatic carriers both had four times the rate compared with healthy controls, suggesting that depression was part of the phenotype rather than a result of a debilitating and stigmatising condition (Heiman *et al.* 2004). Whatever their origin, treatment should also be directed towards helping the patient and his family adjust to the profound emotional problems generated by the distressing and long drawn-out illness. Psychotherapy can sometimes be of considerable assistance (Das & Choudhary 2000). Some bring astonishing powers of adaptation to bear in learning to cope with their severe disablement. The Dystonia Society gives valuable support and information.

Spasmodic torticollis (cervical dystonia)

Spasmodic torticollis is characterised by involuntary spasms of the musculature that lead to repeated dystonic movements of the head and neck, or sustained abnormal postures, or both. The element of sustained spasm in the picture serves in the differentiation from a tic. It may at times represent either a focal or a segmental dystonia, the latter when it spreads to involve the upper limbs.

Clinical features

Females are up to twice as likely to develop the condition, with an onset mainly between the ages of 30 and 50 (Epidemiologic Study of Dystonia in Europe Collaborative Group 1999). Two forms are distinguished (Stacy 2000). Primary (or idiopathic) cervical dystonia may be genetic or sporadic. History, examination and investigations reveal no obvious cause, although it may be part of a wider generalised dystonia. Secondary (or symptomatic) dystonia occurs after trauma, dopamine antagonist drugs or degenerative disease that affects the basal ganglia. The movements are typically irregular, forcible and writhing in character, involving several of the neck muscles along with the upper parts of the trapezii. The sternomastoid is usually prominently involved, drawing the head laterally and rotating the chin in a characteristic manner. Less commonly there may be simple lateral flexion, or the head may be pulled directly forwards (antecol-

lis) or backwards (retrocollis). In time the spasms come to be almost continuous and the affected muscle groups may show considerable hypertrophy. Pain is common, occurring in 70–80% of patients (Chan *et al.* 1991; Muller *et al.* 2002), and contributes much to the associated disability (Lobbezoo *et al.* 1996). Other abnormal movements are occasionally detected: facial twitches and grimaces, blinking, shrugging of the shoulders, or twisting athetoid movements of the upper limbs.

Once the condition is well developed, the patient finds himself powerless to relax the offending muscle groups or to resist the abnormal movements except for short periods of time. The movements are noticeably affected by emotional influences, becoming more powerful and frequent under tension, excitement or distress. Any sudden startle or shock is likely to be followed immediately by a spasm. Self-consciousness usually aggravates the condition, likewise walking or engaging in strenuous activity.

The movements subside during sleep, and may temporarily come under a greater measure of control when the patient is engaged in activities such as eating or drinking. An unexplained but striking feature is the ability of some patients to control the spasms by resting a hand or finger lightly against the chin, and not infrequently on the side away from which the turning movements are made (*geste antagoniste*).

The course is usually slow progression over many years but the outcome is extremely variable (Lowenstein & Aminoff 1988). Some patients are only mildly affected and can continue with their usual occupations, while others become permanently and severely incapacitated. A few show arrest or resolution of the disorder, others show spontaneous remissions varying from a few days to several years. This uncertain natural history adds greatly to the difficulties of gauging the effects of treatment. The picture may also modify as to detail over time, quick movements changing to slower spasms, or spasms giving way to sustained postures. Different muscle groups may come to be implicated, subsequent relapses even involving turning to the opposite side.

Among 103 cases, Patterson and Little (1943) found that 13% pursued a static course, 42% were progressive, 40% were recurrent or intermittent, and two patients had complete remissions without treatment. On follow-up 25% were worse, 12% unchanged, 12% slightly improved, 42% much improved and 7% 'cured'; 10% were unable to work, 49% were partially incapacitated for work and 29% were able to work as well as ever.

Meares (1971) found that patients tended in general to deteriorate in the first 5 years and then become static. After the first 10 years slight improvement might be seen (Dauer *et al.* 1998), those who had had the disability for this length of time often showing considerable adaptation to its effects. Remissions may occur, although research in the area is hampered by the lack of a universal definition of remission

(Friedman & Fahn 1986; Lowenstein & Aminoff 1988; Jahanshahi *et al.* 1990). They are often incomplete and short-lived, and most patients have relapsed by 5 years. The only consistent clinical predictor of remission is younger age of onset (Dauer *et al.* 1998).

Aetiology

Hypotheses about aetiology have been widely divergent, ranging from psychodynamic to organic, with many suggestions that both sets of factors may be at work. The condition is now firmly classified among the dystonias, but that does not entirely end the argument. In some cases the torticollis is clearly intimately related to other dystonic manifestations, whereas in others it develops as an isolated manifestation in a setting of emotional trauma. In the latter it can sometimes be hard to escape the conclusion that psychological factors are primarily responsible, albeit operating in an individual who is constitutionally predisposed.

More recent evidence underlines the organic basis of many cases of cervical dystonia. Genetic factors have been shown to play a role in a number of dystonias, as described above. A familial aspect to cervical dystonia has been highlighted by Uitti and Maraganore (1993) and Defazio *et al.* (2004). In the series of Chan *et al.* (1991), 12% of patients had a positive family history. A mutation on chromosome 18 (DYT7 gene), inherited in an autosomal dominant fashion with incomplete penetrance, has been associated with the development of cervical dystonia in 15 of 18 families in Germany (Leube *et al.* 1997). The discovery of other contributing genes appears highly likely (Jarman & Warner 1998).

Whilst the hypothesis that trauma may be a cause of cervical dystonia is controversial, the prevalence of pain as a symptom has suggested it may contribute to the aetiology (Jankovic 1994). Much of this idea is based on increased recognition of the role played by the basal ganglia in nociception (Jones *et al.* 1991). Evidence of basal ganglia abnormalities has come from functional imaging studies. Galardi *et al.* (1996) have shown that patients with cervical dystonia have greater rates of glucose metabolism in the basal ganglia, thalamus, cerebellum and premotor cortex. Magyar-Lehmann *et al.* (1997) provided supporting evidence with a study showing hypermetabolism in the lentiform nuclei. Naumann *et al.* (1998) showed that patients with cervical dystonia had reduced striatal D₂ dopamine binding compared with healthy controls.

Irrespective of whether psychological factors are causative in cervical dystonia, they are most certainly strongly associated with the disorder. Depression is much more common than in the general population. Nickel *et al.* (1996) found that 24% of their sample were depressed, whilst Muller *et al.* (2002) reported that 15% scored over 18 on the Beck Depression Inventory. Moraru *et al.* (2002) found a similar figure although if milder cases were included the

prevalence was 42%. Neck pain (Muller *et al.* 2002) but not duration of disease (Moraru *et al.* 2002) was associated with depression. Anxiety disorders, including social phobia and generalised anxiety disorder, are also common (Gundel *et al.* 2001, 2003; Lauterbach *et al.* 2003). A number of studies highlight that depression and anxiety often predate the dystonic symptoms and as such they are not simply a reaction to a disability (Moraru *et al.* 2002; Gundel *et al.* 2003; Duane & Vermilion 2004; Lauterbach *et al.* 2004). Patients with cervical dystonia have impaired quality of life to which pain and psychological factors contribute significantly (Ben-Shlomo *et al.* 2002; Camfield *et al.* 2002; Muller *et al.* 2002).

Treatment

Physical methods such as massage, traction or immobilisation in collars and braces usually meet with disappointing results. Attempts at immobilisation commonly lead to bruising and chafing, and any benefit is promptly lost on removal of the restraint.

Drug therapy has also proved disappointing (Adler & Kumar 2000). Anticholinergics such as trihexyphenidyl are sometimes helpful but less so than in the dystonias which set in during childhood. Adults are more prone to side effects, and often cannot tolerate the high dosage required for therapeutic response. Benzatropine, diazepam and neuroleptics such as phenothiazines or haloperidol may help a proportion of patients in the early stages, but benefits are often transient. The treatment that has emerged as most useful is injection of botulinum toxin (Botox, Dysport) into the affected muscle groups (Tsui *et al.* 1986; Stell *et al.* 1988; Blackie & Lees 1990). The use of botulinum A and botulinum B has been reviewed by the Cochrane Collaboration (Costa *et al.* 2005a–d). This should be undertaken only in clinics which have special experience of using the technique. It leads to relief from the neck deviations and associated pain in a high proportion of patients.

Careful choice of injection sites is important, the aim being to weaken the most active muscles from among the sternomastoid, splenius capitis and trapezius. Improvement usually follows within a week. Mild neck weakness may be experienced for some days after the injections, also dysphagia that may persist for a week or two and nausea (Jankovic & Schwartz 1991). The beneficial effect typically lasts for 2–4 months, after which repeat injections become necessary. The affected neuromuscular junctions are permanently inactivated, the waning of effect resulting from the establishment of new junctions by a process of sprouting from presynaptic axons. Experience has shown the feasibility of continuing treatments over many years, although antibodies to the toxin may ultimately develop and lead to unresponsiveness. The toxin appears to act by cleaving a membrane-bound protein required for release of acetylcholine. Most treatment is with botulinum type A. Studies have shown that in most cases treatment can be given success-

fully over many years (Brashear *et al.* 2000; Hsiung *et al.* 2002). Although less than 2% cease treatment due to intolerable side effects, 7.5% can develop a secondary unresponsiveness. Botulinum toxin exists in a number of serotypes: type A and type B both block the action of acetylcholine, but by binding to different receptors. The use of type B appears effective even in patients resistant to type A. The use of type F is currently being explored.

Alternative approaches have included intensive behaviour therapy employing massed practice, aversion techniques or systematic desensitisation to the anxiety induced by the head movements (Agras & Marshall 1965; Brierley 1967; Meares 1973). Biofeedback may meet with substantial success in certain patients, either as an aid to simple relaxation or more directly by electromyographic feedback from the offending muscle groups (Korein & Brudny 1976; Fischer-Williams *et al.* 1981). Psychotherapy directed at the exploration of conflicts, or analysis of the settings in which the movements first appeared, has been reported to produce improvement and even complete relief in occasional patients (Whiles 1940; Paterson 1945). Surgical approaches have included selective division of cervical nerve roots, peripheral denervation, thalamotomy and even sternomastoid myotomy in very disabled patients, but the advent of treatment with botulinum toxin should reduce the need for such invasive procedures.

Blepharospasm and oromandibular dystonia (cranial dystonia, orofacial dystonia)

Blepharospasm consists of an uncontrollable tendency to spontaneous and forcible eye closure. It may begin unilaterally but both eyes are usually soon affected (Malinovsky 1987). Repeated contractions of the orbicularis oculi can progress to almost constant involuntary spasm, sometimes rendering the patient virtually unable to see. Spasms are provoked by bright light, embarrassment, attempts at reading or looking upward. Facial grimacing may be extensive in the effort to keep the eyes open. Some patients find tricks that help: yawning, humming, touching the eyelids or eyebrows, neck extension or forced jaw opening. All spasms disappear during sleep.

It is most common in middle-aged or elderly women, with onset particularly in the sixth decade. Its prevalence is 1.2–5 per 100 000 but there is some evidence of marked geographical differences, for example high rates in northern Italy (Muller *et al.* 2002; Defazio *et al.* 2004). For some considerable time, even years, it may be intermittent, and the aggravation by emotional influences may give a strong impression that psychological factors are operative. A considerable proportion of patients show depression around the time of onset (Marsden 1976a). The affected patients are typically stable, however, and without precipitants that could explain the disorder (Bender 1969).

Oromandibular dystonia has a similar range of onset and also more frequently affects women than men. Prolonged spasms affect the muscles of the mouth, jaw and sometimes the tongue (lingual dystonia). They last for up to a minute and are repetitive but irregular in timing. The lower perioral muscles and the platysma may also be involved. The jaw may be forced open or abruptly closed, the lips purse or retract, and the tongue protrudes or curls within the mouth. Severe grimacing occurs and talking and eating may be rendered difficult. The condition can cause great social embarrassment. Spasmodic dysphonia and dysphagia may also be present.

The picture can at first sight resemble the orofacial dyskinesias seen as a late effect of neuroleptic medication (see Tardive dyskinesia, under Drug-induced disorders/Clinical pictures, earlier) but in essence the movements are different (Marsden 1976a,b). Orofacial dystonia consists of repetitive prolonged spasms rather than the incessant flow of choreiform lip smacking, chewing and tongue rolling movements seen in tardive dyskinesia.

The spasms are typically provoked by embarrassment, fatigue or attempts at speaking, chewing or swallowing. Certain tricks may be learned to abort them, such as grasping the lower jaw firmly or shaking the head. In the early stages the capricious nature of the spasms may produce bizarre results, for example one of Marsden's (1976a) patients could not speak without provoking spasms but could sing normally, and in another where the reverse was obtained.

While each of these two disorders can be seen in isolation, there is a strong tendency for them to be coupled together. Marsden's (1976a) composite material showed blepharospasm alone in 13 cases, oromandibular dystonia alone in 9, and both together in 17. In a later series of 264 patients with blepharospasm, 188 (71%) also showed oromandibular dystonia (Grandas *et al.* 1988). When both are present they usually begin contemporaneously, although sometimes the blepharospasm antedates the oromandibular dystonia by several years. The composite picture has been labelled Meige's syndrome, or Brueghel's syndrome, since both aspects are well depicted in the famous painting, Ben Simon and McCann (2005) suggest that isolated blepharospasm occurs only in a minority of patients. Most have a combination of blepharospasm with oromandibular dystonia or a segmental cranial dystonia. Patients may also exhibit frowning, torticollis, titubation, or hyperexcitable trigeminal reflex blinks (Mauriello *et al.* 1996). Spasms are often absent during sleep (Shorr *et al.* 1985).

The course is usually chronic and protracted, but can be intermittent over many years. Blepharospasm remains mild in some 20% of cases, whereas other patients become profoundly disabled (Tolosa & Martí 1988). Grandas *et al.* (1988) found that some 10% of patients with blepharospasm had experienced a partial or complete remission, lasting from months to several years, but with ultimate recurrence in the

great majority. Half of Marsden's (1976a) patients with both blepharospasm and oromandibular dystonia progressed to dystonia elsewhere: torticollis, dystonic posturing of the arms, respiratory spasms or flexion spasms of the trunk.

Aetiology

The aetiology of both conditions remains obscure, but they are now firmly included within the dystonia spectrum. Blepharospasm was formerly often considered to be psychological in origin, but its frequent association with oromandibular dystonia has served to dispel this view. An organic basis is supported by its emergence as a side effect of treatment with neuroleptics or levodopa, and its occasional development in Parkinson's disease or as a sequel to encephalitis lethargica. Similar associations apply to oromandibular dystonia, which may also accompany Wilson's disease. In both conditions the nature of the spasms – prolonged, repetitive and irregular in timing – is typical in all respects of other dystonias.

Functional neuroimaging has demonstrated increased metabolism in the thalamus and striatum (Esmaili-Gutstein *et al.* 1999; Schmidt *et al.* 2003). Baker *et al.* (2003), also using functional MRI, suggest that the cortical and subcortical areas, including the limbic system and the cerebellum, involved in normal blinking may show increased activation. Several authors focus on basal ganglia abnormalities as the cause of blepharospasm (Berardelli *et al.* 1985; Schicatano *et al.* 1997), probably in combination with an alteration in the trigeminal sensorimotor system. The response of one patient to cannabinoids (Gauter *et al.* 2004) suggests a possible role for central GABAergic and glutaminergic systems.

Continuous chronic blepharospasm has also been reported after head injury or subarachnoid haemorrhage, or in association with cerebral tumours, degenerative conditions or cerebral arterial disease. Rostral midbrain lesions appear to be particularly closely related to its development (Poewe *et al.* 1989). In all such settings blepharospasm can sometimes resemble a psychogenic disorder but for the history and abnormal findings on neurological examination. In the large group of patients reported by Grandas *et al.* (1988), dystonia was observed in other parts of the body in 78% of cases: oromandibular dystonia in 71%, torticollis in 23%, laryngeal dystonia in 17%, respiratory dystonia in 15%, arm or hand in 10%, pharyngeal in 7%, trunk in 2% and leg or foot in 2%. A postural tremor was evident in the arms in 12%. A family history suggestive of blepharospasm or dystonia elsewhere was found in almost 10% of cases, suggesting a genetic predisposition. A variety of *gestes antagonistes* appear effective for many patients. These include talking, singing, yawning, whistling, coughing, humming, or placing a finger on the lateral margin of the orbit (Anderson *et al.* 1998).

Although there is now overwhelming evidence of an organic basis for blepharospasm, it is also clear that symptoms may be triggered or exacerbated by psychological factors, and that comorbid psychiatric diagnoses are

common. Muller *et al.* (2002) examined 89 consecutive patients attending a specialist clinic and found that 37% were depressed, almost half of these at least moderately. Women were more depressed than men. Wenzel *et al.* (2000) studied a smaller group using the Structured Clinical Interview for DSM-IV and found that 71% had a current or lifetime psychiatric diagnosis; 32% had major depression or recurrent depressive disorder.

Treatment

Treatment can raise very considerable problems as responses to drug treatment are often ill-sustained. With both blepharospasm and oromandibular dystonia there may be a good response to anticholinergic medication provided this can be tolerated in adequate dosage. Levodopa and lisuride helped a proportion of Grandas *et al.*'s patients with blepharospasm. Tetrabenazine, lithium, benzodiazepines or neuroleptics such as haloperidol and pimozide are also often tried. Severe cases of blepharospasm may require section of branches of the facial nerve, or muscle-stripping operations to remove selected parts of the orbicularis oculi muscles.

Injection of botulinum toxin into the orbicularis oculi muscle is now the first-line treatment for blepharospasm. Peak effects occur within 5–7 days. The mean duration of benefit is approximately 3 months but can be as long as 6 months (Dutton & Buckley 1988). There is a suggestion that in the long term drug therapy and even eyelid surgery may augment the effects of botulinum toxin (Mauriello *et al.* 1996). Systemic adverse effects are very rare. Local or regional side effects occur though rarely. These include ptosis, diplopia, perioral asymmetry and dysphagia.

Other dystonias and spasms

Other forms of dystonia rarely present to psychiatrists, although laryngeal dystonia may sometimes suggest a hysterical aphonia. In the adductor type the voice is choked and strangled, whereas with the abductor type it is breathy and effortful with whispered segments. Drugs are of little help, but skilled botulinum injections can again give substantial relief. Pharyngeal dystonia presents with difficulty in swallowing, and respiratory dystonia with difficulty in breathing. For details neurological textbooks should be consulted. Hemifacial spasm consists of twitching, tonic spasm and often synkinesis of the muscles innervated by the facial nerve. Though not a dystonic manifestation, this too can now be treated effectively with botulinum injections to the facial muscles (Brin *et al.* 1995). Other than this, the spasms can be helped in some degree by phenytoin, carbamazepine or clonazepam.

Gilles de la Tourette's syndrome (Tourette's syndrome)

Gilles de la Tourette's syndrome, though relatively rare, has attracted a good deal of attention, chiefly on account of the striking nature of the clinical picture. Multiple tics are

accompanied by forced involuntary vocalisations that can sometimes take the form of obscene words or phrases (coprolalia). One of the chief interests of the condition has centred on this verbal component, which has been interpreted as giving a clue to the underlying psychopathological mechanisms. However, our knowledge of the biological basis for this condition is increasing.

Clinical features

Valuable reviews of the clinical picture are presented by Shapiro *et al.* (1978), Lees (1985) and Robertson (1989, 1994). The DSM-IV criteria for diagnosis of the syndrome are as follows:

- presence of both multiple motor and one or more vocal tics at some time during the illness (though not necessarily concurrently);
- such tics occur many times a day, nearly every day or intermittently for more than a year and without a tic-free period exceeding three consecutive months;
- onset before the age of 18 years;
- marked distress or significant impairment in social or occupational functioning occasioned by the disorder;
- absence of general medical conditions or substances such as stimulants that could account for it.

Hanna *et al.* (1999) suggest the prevalence is 0.7%. Patients referred for specialist help can certainly be markedly disabled, but it has become increasingly clear that the majority of sufferers are only mildly affected and unknown to health professionals (Robertson & Gourdie 1990). Many of the latter would therefore fail to meet the DSM-IV criteria completely. The failure to identify mild cases thus limits the accuracy of prevalence data. A study of Israeli army recruits found a prevalence of 4.3 per 1000 (Apter *et al.* 1993), but in a study of UK schoolchildren the figure was 1.85% (Hornsey *et al.* 2001).

The condition is a good deal commoner among boys than girls, in a ratio of approximately 3:1 (Spencer *et al.* 1999). Onset is rare after 11, the great majority beginning between the ages of 3 and 8. In these respects the syndrome resembles the generality of tics in childhood. Motor tics tend to begin around the age of 7, vocal tics some 4 years later, and coprolalia at the time of puberty. Very occasional examples have been reported with onset in adult life (Marneros 1983), though of course these do not conform to the full DSM-IV criteria above.

Tics are simple non-purposeful movements of functionally related muscle groups. They can be divided into simple and complex tics. Simple tics include (i) clonic tics such as eye-blinking, (ii) tonic tics such as arm-stretching and (iii) dystonic tics such as grimacing. Complex tics tend to appear semi-purposeful, for example touching parts of the body or grooming behaviours. Vocal tics may also be simple, due to contractions of the respiratory, laryngeal, oral or nasal musculature (e.g. sounds and grunts), or complex (e.g. words or phrases). Tics may be preceded or accompanied by

sensory phenomena such as unusual bodily sensations or an irresistible urge to move. These are relieved by the movement of the tic (Kurlan *et al.* 1989; Leckman *et al.* 1993; Marcus & Kurlan 2001; Banaschewski *et al.* 2003; Kwak *et al.* 2003). They are distinct from chorea and other abnormal motor movements in their stereotyped pattern, the same event occurring time and again, and in the ability of the subject to hold the movements in check for a short while at the expense of mounting inner tension.

Simple tics are usually the first manifestation. They usually commence around the eyes or in the face, head and neck, spreading later to the limbs and trunk. Before long there are typically multiple tics, often of great force and severity: blinking, grimacing, jerking of the head, shrugging of the shoulders or jerks of the arms and legs. Whole body movements may be involved, leading to bending, jumping, skipping, hopping, stamping or twirling. Compulsions to touch or smell objects, smelling the hands, or to hit and strike objects or the subject's own body are often observed. Complex coordinated movements occasionally appear, such as brief slapping of the face or thighs, or wringing of the hands. The picture may at times be highly bizarre, and the detailed pattern may change over time.

Vocalisations can occur from the outset but are usually added later. Most begin within 5 years of onset. At first they are often inarticulate sounds – sniffs, grunts, barks, throat clearing, snorting or coughing noises that accompany the motor movements. These may then progress to the enunciation of words, sometimes muttered and barely discernible but sometimes loudly and clearly articulated. The vocal tics commonly occur at the end of sentences or clauses, without impairing the overall speech rhythm.

Common oaths and expletives are frequently involved, or brief obscene phrases of aggressive or sexual content (coprolalia). The obscenities are often uttered loudly, with an unusual cadence or pitch, and sometimes with imprecise pronunciation of phonemes (Lees 1985). The coprolalia occurs without any appropriate stimulus, and in common with other vocal tics it usually breaks through in the pauses between sentences. Some patients repeatedly utter the same swear word over and over again, or use long strings of elaborate obscenities. About one-third of patients also utter emotionally charged words of great personal significance, again often spoken oddly with unusual emphasis on particular syllables. One of Lees' patients would occasionally shout the word 'cat', and another 'Elvis'.

The utterance of obscenities commonly sets in at about the time of puberty, but may start as early as 10 or be delayed until well into adult life. It ultimately develops in perhaps one-third of patients reported from clinic samples, though with great variation in different reports. Among sufferers generally it is probably quite rare. Stern *et al.* (2005) suggests a prevalence of only 10%, much less common than echolalia and palilalia. 'Mental coprolalia' in the form of a compulsion to think obscenities is perhaps commoner than overt

coprolalia, and transition from the former to the latter may be observed. Copropraxia is the involuntary and inappropriate making of obscene gestures, the commonest in the UK being the palm-backed 'V' sign. Non-obscene socially inappropriate comments (and behaviours) are now also recognised (Kurlan *et al.* 1996).

It has been shown that when computer programs generate letters or phonemes in a random manner, second- and third-order texts appear increasingly more like English language (Nuwer 1982). There is also an unexpected repeated occurrence of physical obscenities, which by the fourth order of processing have largely disappeared. Similar results are obtained with second-order German. Thus coprolalia in Gilles de la Tourette's syndrome may conceivably result from a 'short-circuiting' in brain function, leading to the production of high probability strings of phonemes out of proportion to other words.

Both the tics and the utterances are affected by emotional stress, becoming more severe with anxiety, excitement, anger, boredom or self-consciousness. The patient may struggle greatly to conceal the coprolalia, disguising or distorting obscene words so that their true nature is not at first detected. Intense efforts at control may succeed for a while, but at the expense of mounting inner tension and ultimately an explosive recrudescence. The coprolalia tends to cease when the patient is alone but the tics do not. Both are often markedly relieved by alcohol. In the past, tics were said to cease or diminish markedly during sleep; however, they can persist during sleep (Rothenberger *et al.* 2001) and have even been observed to increase during REM sleep (Cohrs *et al.* 2001). They disappear during sexual arousal (Shapiro *et al.* 1973). They usually diminish during periods of intense concentration or when the patient is firmly preoccupied with matters that do not arouse anxiety. Jankovic (2001) points out that tics may actually increase with relaxation following a period of stress, for example on coming home after a day at school. He described these as 'releasing tics'.

Echo-phenomena have often been stressed in the literature but occur in less than one-third of cases. There may be compulsive repetition of words spoken by others (echolalia) or compulsive imitation of actions (echopraxia).

The intelligence of affected persons varies widely but in some series a surprising number have shown superior ability. Most studies have shown the distribution of intelligence to be within normal limits (Singer 2005). Robertson (1989) reviews studies that have looked for evidence of specific impairments, noting that language skills appear to be essentially unimpaired whereas visuopractic deficits have emerged with fair consistency. As a result significant discrepancies have often been observed between verbal and performance IQ scores. Attentional deficits have also been highlighted, and may account for Tourette children often falling behind their peers at school despite normal intellectual ability. Channon *et al.* (1992) made comparisons between adult patients with the disorder and matched controls on a

variety of attentional tests, demonstrating significant impairments on serial addition, block span sequence, Trail-making and several vigilance tasks. Impairment was found both in sustaining attention and in focusing and shifting sets between salient stimuli. Such deficits were not explicable in terms of depression, anxiety or obsessiveness, and showed no relationship to the dosage of drugs taken. The syndrome is more common in children with autistic spectrum disorder (Baron-Cohen *et al.* 1999), although this is not related to the severity of the autistic symptoms.

Other features that have often been claimed include a high prevalence of childhood neurotic symptoms and disturbed family backgrounds, but proper controlled comparisons are not available. Similar difficulties surround the reports of antisocial behaviour and conduct disorder in a high proportion of patients, including lying, stealing and aggressive behaviour generally. Inappropriate sexual behaviour, including exhibitionism, has also sometimes been stressed.

A high prevalence of self-injurious behaviour has occasionally been reported, including head banging, lip biting and pummeling of the head and chest (Robertson 1992). More serious but rare instances include eye damage and touching hot objects. The precise prevalence depends on the definition of the injury caused. Hence in a study of 3500 patients, Freeman *et al.* (2000) found a rate of 14%, whereas Robertson (2000) reports 25%, Stern *et al.* (2005) approximately 33% and Mathews *et al.* (2004) 60%. Self-injurious behaviour is more likely if the patient has an additional psychiatric diagnosis (Freeman *et al.* 2000). Mathews *et al.* (2004) distinguished a 'severe' form, associated with impulse control problems, found in only 4% of cases.

More convincing associations have emerged with behavioural disturbances antedating the appearance of the syndrome, including attention deficit hyperactivity disorder (ADHD). These are often the symptoms for which patients are referred to a physician. In Freeman's cohort of 3500 patients, ADHD occurred in 31–91% (Freeman *et al.* 2000). Occurrence of ADHD is not associated with severity of the tic disorder, although ADHD symptoms are common in severe disease (Robertson & Stern 1998). Knell and Comings (1993) found that ADHD was more common in the siblings of children with Tourette's syndrome and suggested that there may be a common genetic basis for the two conditions. The additional burden of ADHD symptoms impacts substantially on the psychosocial difficulties of Tourette's patients (Bawden *et al.* 1998; Carter *et al.* 2000; Sukhodolsky *et al.* 2003).

Sleep disturbances including nightmares, somnambulism and night terrors have occurred in up to one-third. There is also some evidence that depression and anxiety may be more common in adults with the disorder than in the normal population (Robertson *et al.* 1988, 1993). Freeman *et al.* (2000) reported that 20% had depression and 18% anxiety. There is little to suggest any special relationship with psychotic illness, though not surprisingly there have

been occasional reports of patients with bipolar affective disorder or schizophrenia.

Increasingly, however, there is evidence of a close association with obsessive-compulsive disorder, to the extent that this is sometimes regarded as an integral part of the condition, perhaps with a shared genetic predisposition. In addition to ritualistic behaviours and compulsions to touch objects, a high proportion of patients report obsessional thoughts and activities. These sometimes amount to frank obsessive-compulsive illness. Frankel *et al.* (1986) found that half of their patients had significantly elevated scores on a questionnaire for obsessional-compulsive symptoms, many scoring as highly as patients with obsessive-compulsive illness. Robertson *et al.* (1993) similarly showed elevated scores on the Leyton Obsessional Inventory. Obsessional features were observed in two-thirds of the patients reported by Nee *et al.* (1982) and Montgomery *et al.* (1982). The latter study also found a high prevalence of obsessive-compulsive illness among the first-degree relatives of patients. Obsessive compulsive behaviours were present in 32% of Freeman *et al.*'s (2000) cohort, whilst Scahill *et al.* (2003) suggested that up to 89% of patients showed obsessive-compulsive behaviours.

Caine *et al.* (1988) found that almost half of the children in their epidemiological survey had obsessional ideas, often with associated ritualistic motor behaviour. The commonest included 'evening up', whereby a series of rituals ensured that the body was symmetrical and balanced, also counting games and touching rituals to ward off bad omens. Coffey *et al.* (1998) and Cath *et al.* (2000) also report on the need for symmetry and 'doing things right'. Cummings and Frankel (1985) drew attention to certain similarities between the syndrome and obsessive-compulsive disorder, including age of onset, lifelong course with waxing and waning, involuntary intrusive experiences and worsening with depression and anxiety. They advanced the hypothesis that the tics and vocalisations of Gilles de la Tourette's syndrome may be aberrant manifestations of simple motor programmes generated in the basal ganglia, and that obsessions and compulsions represent more complex motor plans initiated by similar anomalous neural activity. Obsessive-compulsive behaviours in adults are associated with ADHD and self-injurious behaviour (Eapen *et al.* 2004), whilst in children they are associated with impulsive and aggressive behaviour (Banaschewski *et al.* 2003).

Course and outcome

Over time the severity of the disorder tends to wax and wane, periods of partial remission alternating with exacerbations. The symptomatology may also change as to detail, new tics developing as old ones disappear. Occasionally there may be periods lasting for days or weeks during which the movements remit completely.

Firm information about the longer-term outcome is hard to obtain since there have been few prolonged follow-up studies. Leckman *et al.* (1998) reviewed a cohort of 36 patients for tic severity in the first two decades. Half the patients were free of tics by the age of 18. It seems that the disorder may ameliorate in early adult life, and coprolalia has been said to remit in about one-tenth of subjects without medication (Shapiro *et al.* 1978). Bruun and Budman (1992) report a rather more encouraging picture. Of 136 patients who were followed for 5–15 years, 59% had been rated as mild to moderate when first encountered, but at follow-up 91% were now in these categories. More than one-quarter had discontinued medication and most others were on lower doses than originally required. Half stated that they had improved spontaneously, most commonly in their late teenage years. A review of several studies suggested that some 30–40% of cases may remit completely by late adolescence, though it cannot be judged whether such remissions are permanent. Symptoms in adulthood appear more stable; 65% of patients studied by de Groot *et al.* (1994) had shown no change in symptoms in the past 5 years. Anecdotal evidence indicates that elderly Tourette patients rarely exhibit severe symptoms, and it is noteworthy that there have been few reports of elderly patients with the disorder.

The social impact of the illness, at least in the early years, is often disastrous. Some patients withdraw to a considerable extent, while others appear to maintain surprisingly good work records and social relationships despite their disability. Some patients remain only mildly affected throughout, clinical impressions of the gravity of the disorder being influenced by those referred for specialist help. Elstner *et al.* (2001) studied 90 adult patients and found that their quality of life was poor overall. Factors associated with this poor quality of life were employment status, tic severity, obsessive-compulsive behaviours, anxiety and depression.

Nosology and aetiology

Different views have been put forward about the nosological status of the condition. Some regard it as a rare and distinct disease entity, while others view it as merely the most severe and persistent presentation of the tic syndrome in childhood.

Gilles de la Tourette (1855) himself allied the condition with certain other rare motor and speech disorders reported from various parts of the world: the 'latah' reaction among Malays, the 'myriachit' of Siberia, and the 'jumping Frenchmen of Maine'. It is now realised, however, that this was erroneous. Latah is manifest as echopraxia, echolalia and coprolalia but tic-like phenomena do not occur. Automatic obedience is a prominent feature. It is essentially a severe startle reaction and does not occur without a provoking stimulus. Yap (1952) regards it as a culturally determined fear response found only in primitive cultures where

persons have limited powers of control over the environment. Myriachit is similar. The Jumpers of Maine displayed analogous features as part of a religious ritual.

Psychogenic theories

Psychogenic theories regard emotional traumas and conflicts as fundamental to the genesis of tics. Emotional precipitants can sometimes be discerned at the time of onset, and a high prevalence of psychiatric disturbance has been reported in patients and their families. The tics are seen as the direct or symbolic expression of emotional disturbance, aggression, anxiety or the handling of sexual conflicts.

Psychoanalysts have conceived of tics as the involuntary motor equivalents of emotional activity, allowing repressed impulses, usually of a sexual or sadistic nature, to make their appearance in disguised form (Fenichel 1945). Such impulses have become 'independent of the organised ego', that is to say they lack the normal integration with the totality of the personality. In a similar vein, Mahler and Rangell (1943) regarded the symptoms of Gilles de la Tourette's syndrome as expressing the conflict between erotic and aggressive drives on the one hand and internalised censoring controls on the other.

These psychoanalytic conceptions may not seem particularly convincing when applied to tics generally, but it is interesting that in Gilles de la Tourette's syndrome one may meet with vocal and verbal manifestations that lend some support to such views. The noises can often be construed as aggressive or erotic in character, while coprolalia displays such themes in unmistakable form. Morphey and Sim (1969) argued strongly for a psychogenic aetiology for Gilles de la Tourette's syndrome, noting precipitating factors that were largely psychological in nature, and the improvements that could be seen after psychotherapy, leaving home or admission to hospital. However, susceptibility to psychological influences need not imply that these are causative. It would seem wiser merely to conclude that Gilles de la Tourette's syndrome may reveal psychodynamic factors at work in an unusually clear fashion, rather than to grant them a primary role in the genesis of the disorder. Some observers with wide experience of the condition have been unable to find evidence of inhibition of hostility or other special personality characteristics, and suggest that any observed psychopathology is most likely to be a product of the illness rather than playing a causative role (Shapiro *et al.* 1972).

Learning theory

The learning theory model views tics as conditioned avoidance responses which have originally been evoked in a traumatic situation, then reinforced by the reduction of anxiety that follows (Yates 1958). Because of stimulus generalisation, the anxiety that the tic reduces will eventually be provoked by many more situations so that the tic becomes an increasingly stronger habit. In essence the tic is a simple learned response that has attained maximal habit strength.

Corbett (1971) pointed out that there is a striking similarity between tic movements and the movements seen in the startle response. This applies to both the nature of the movements and their distribution. Thus tics most frequently involve blinking, the face, head and neck, and the limbs, in that order, which parallels the distribution of motor activity during startle. Startle responses, moreover, are sometimes associated with vocalisation, and are easily conditioned to neutral stimuli.

Even if such a model is felt inadequate to explain the origin of the tic, it is easy to see how secondary reinforcing properties may come to attach to it and help to perpetuate the habit. To the extent that problems of aggression and hostility are prominent in patients with Gilles de la Tourette's syndrome, the effects of their behaviour on others may sometimes powerfully gratify the habit. Behavioural treatment based on the learning theory model has met with some success, though apparently less so with Gilles de la Tourette's syndrome than with simple motor tics.

Developmental theories

A developmental defect has been proposed as the basis of tics and derives support from certain indirect evidence. Such a conception presupposes no necessary special nexus of psychological conflict in the patient, nor some covert form of acquired brain damage, but merely that the normal maturational processes of control over motor movements have not been fully achieved. The patient is accordingly vulnerable to faulty conditioning procedures as set out above, or if he is destined for emotional disturbance his neurosis will be liable to choose the form of a tic on account of his motor lability.

Much of the evidence presented by Corbett *et al.* (1969) fits with a conception of developmental defect. The preponderance in boys accords with their proneness to other developmental disorders. The restricted age of onset between 6 and 8 years suggests a developmental defect, similarly the marked tendency for simple tics to remit at adolescence. Corbett *et al.*'s patients showed an excess of other developmental disorders, such as encopresis and speech defects, compared with the clinic population generally.

It is less clear whether developmental failure could account for the genesis of the more florid manifestations of Gilles de la Tourette's syndrome. The frequency of a family history of simple tics argues in favour of some form of constitutional motor lability, but the tendency for the syndrome to persist through adolescence and indeed well into adult life would suggest that more than developmental immaturity is involved.

Organic theories

Organic theories presuppose that some specific brain disorder contributes directly to the development of tics, and various biochemical, neuroimaging and genetic studies contribute to the conclusion that Gilles de la Tourette's syn-

drome is an inherited developmental disorder of synaptic neurotransmission resulting in disinhibition of the cortical–striatal–thalamic–cortical system. Pasamanick and Kawi (1956) explored the possibility of brain damage resulting from prenatal or perinatal factors by identifying 83 children with tics and tracing the birth records of each. When compared with the next child born, matched for sex, race, maternal age and place of birth, the frequency of complications of pregnancy and parturition was found to have been significantly higher among the children with tics. A number of perinatal factors have now been associated with an increased risk of Tourette's syndrome. These include severe first-trimester nausea, severe maternal stress during pregnancy, maternal use of caffeine, alcohol and tobacco during pregnancy, being an identical twin with a lower birthweight, and transient hypoxia during birth (Leckman 2002).

The success of treatment with dopamine-blocking agents, and the occasional emergence of a not dissimilar syndrome along with tardive dyskinesia after long-term neuroleptic medication (De Veaugh-Geiss 1980; Mueller & Aminoff 1982), point to dopaminergic hypersensitivity as a possible mechanism. The observations that Tourette patients have a higher blink rate at rest and an exaggerated audiogenic startle response also suggest a dopaminergic abnormality (Stell *et al.* 1995; Tulen *et al.* 1999; Gironell *et al.* 2000), although investigations of genetic links to dopamine receptors have repeatedly been negative (Brett *et al.* 1995). Caine (1985) reviews several neurochemical investigations into the disorder, some showing reduced cerebrospinal fluid levels of homovanillic acid, the major metabolite of dopamine, but such findings have been questioned on methodological grounds. More recently, Singer and colleagues have reported increased numbers of presynaptic dopamine carrier sites in the striatum in three Tourette patients studied at autopsy, and also reductions of cyclic AMP in the cerebral cortex (Singer *et al.* 1991; Singer 1992, 2000).

Brain imaging studies support the presence of subtle cerebral defects. Abnormalities in the size of the caudate nucleus and asymmetries in other basal ganglia structures have occasionally been reported (Hyde *et al.* 1995; Peterson *et al.* 2001; Swerdlow & Young 2001). Volumetric MRI studies show changes in the premotor, prefrontal and orbitofrontal areas in boys (Peterson *et al.* 1993). PET and SPECT have indicated hypoperfusion in the basal ganglia, thalamus, frontal and temporal cortex (Braun *et al.* 1995; Crespo-Facorro *et al.* 1999; Stern *et al.* 2000), and possibly decreased availability of striatal D₂ receptors (Chase *et al.* 1986; Riddle *et al.* 1992; Robertson 1994; Moriarty *et al.* 1995). Neurophysiological studies have shown that Tourette patients fail to manifest cortical electrical potentials preceding their simple tics, whereas they have a normal pre-movement negative potential (Bereitschaftspotential) when they voluntarily mimic the same movements (Obeso *et al.* 1981). This suggests that the tics are not generated through the normal cortical motor pathways utilised in willed movement but have a subcorti-

cal origin. Recent work has focused on the neural substrates of habit formation, most notably differential metabolic activity in cortical neurones projecting into the striatum. The area is reviewed by Leckman (2002).

Genetics

Though the disorder is often sporadic, recent studies have increasingly supported a genetic contribution, with links between narrowly defined Gilles de la Tourette's syndrome, chronic multiple tics without vocalisations, and obsessive–compulsive disorder. The precise genetic mechanisms remain unclear, but the presence of a single autosomal gene with varying penetrance has been suggested by some investigators. Polygenic inheritance is another possibility, and X-linked modifying genes may account for the increased prevalence among males.

Price *et al.* (1985) investigated 30 monozygotic and 13 dizygotic pairs of same-sex twins where at least one co-twin had Gilles de la Tourette's syndrome. The concordance rates were 53% in the former and 8% in the latter. When the criteria were broadened to include tics of any sort, the concordances rose to 77% and 23% respectively. The lack of full concordance among monozygotic pairs emphasises the additional role of non-genetic factors, and Leckman *et al.* (1987) were able to show that in non-concordant pairs the unaffected co-twin always had the higher birthweight. This suggests that prenatal events or exposures may have played a part in actualising the disorder.

Large family studies have shown an increased prevalence of Gilles de la Tourette's syndrome and of chronic multiple tics in the relatives of probands, segregation analysis sometimes suggesting the presence of a major autosomal gene with incomplete penetrance (Robertson 1989). Family studies have also indicated that the same gene may be expressed as obsessive–compulsive disorder. Thus many relatives of Tourette patients describe obsessional–compulsive thoughts and actions in the absence of tics or vocalisations (Robertson 1989), and obsessive–compulsive disorder has been found to be especially common among family members where Gilles de la Tourette's syndrome appears to be an inherited disorder (Cummings & Frankel 1985). Family aggregations have been confirmed in two particularly large pedigrees, one of 122 members from six generations in a British family (Curtis *et al.* 1992) and one of 161 members over four generations in the USA (McMahon *et al.* 1992). More recently, studies on a large French-Canadian family showed linkage on the long arm of chromosome 11 (Merette *et al.* 2000). Sib-pair analysis by the Tourette Syndrome Association International Consortium for Genetics (1999) identified two possible locations on chromosomes 4 and 8, whilst a study of a South African family identified possible areas on chromosomes 2 and 8 (Simonic *et al.* 1998, 2001). Thus while the exact mode of inheritance remains to a large extent uncertain, both family and genetic studies combine to

suggest that there is a spectrum of disorder, extending from classic examples of the syndrome to other forms of tic and including also obsessive–compulsive disorder.

A new line of investigation has been the possible role of childhood infection (Allen *et al.* 1995; Hallett *et al.* 2000). Elevated titres of antibodies to group A β -haemolytic streptococci have been found in some patients (Swedo *et al.* 1997). Tourette's was one of a number of disorders included within the category 'paediatric autoimmune neuropsychiatric disorders associated with streptococcus' (Swedo *et al.* 1998). Church *et al.* (2003) found high levels of anti-basal ganglia antibodies in a group of UK patients, of whom 91% also had raised antistreptolysin O titres. However, there is a growing consensus that a postinfective aetiology accounts for only a small proportion of patients with Tourette's. There appears to be no relationship between the presence of anti-neuronal antibodies and age of onset or severity of tics (Singer *et al.* 1998). Two prospective longitudinal studies have shown no clear link between new group B streptococcal infection and either the development or exacerbation of tic or obsessive–compulsive symptoms (Luo *et al.* 2004; Perrin *et al.* 2004).

Treatment

Until the advent of pharmacotherapy the treatment of Gilles de la Tourette's syndrome was mostly disappointing. Moreover, it was difficult to evaluate the effectiveness of interventions on small numbers of cases because of the tendency of the disorder to show spontaneous fluctuations.

Psychotherapy often met with failure but improvements were sometimes reported, very occasionally with seeming total recovery (Mahler & Luke 1946; Eisenberg *et al.* 1959; Kurland 1965). Nevertheless, supportive psychotherapy and group counselling procedures find an important place in helping patients to cope with their disability. Abreaction has been attempted with a wide range of drugs, and Michael (1957) reported a patient who underwent a striking remission after a series of carbon dioxide inhalations when intensive psychotherapy had met with no response.

The main aim of tic treatment is not to abolish tics entirely, but rather reduce the frequency to the point where normal function is possible. Behavioural therapy can be effective with simple tics, for example 'massed practice', which is based on the theory that voluntary practice of the tics for long periods of time will build up reactive inhibition to their recurrence (Yates 1958). Clark (1966) reported remarkably good results with the technique in two of three cases of Gilles de la Tourette's syndrome. Coprolalia was eliminated by asking the patient to repeat the most frequently used obscenity as often as possible in a large number of treatment sessions. Others, however, have had less success, finding that practice may aggravate the tics by generating increased anxiety (Sand & Carlson 1973). Techniques in which the patient is taught to practise movements incompatible with

the tic, or to substitute a neutral word for an obscenity, have also occasionally helped (Friedman 1980). Cohen and Marks (1977) have reported the value of an operant conditioning programme, involving rewards for tic-free periods of increasing length, which can be implemented in the patient's home. Behavioural techniques also find a special place in the management of severe obsessive–compulsive behaviour when this is part of the condition.

Drugs such as diazepam may help temporarily by reducing anxiety, but dopamine receptor antagonists emerged as the first truly valuable medications. Connell *et al.* (1967) convincingly showed the effectiveness of haloperidol in simple tics in a double-blind comparison with diazepam, and Chapel *et al.* (1964) were among the first to report excellent results in Gilles de la Tourette's syndrome. Haloperidol has since received enthusiastic support and remains among the drugs of first choice. Shapiro and Shapiro (1982) conclude that over 80% of patients gain improvement, though some 13% discontinue it because of side effects. Dysphoria and sleepiness can be troublesome and may outweigh the benefits in terms of tic control. A start is usually made with very small dosage, for example 0.25–0.5 mg daily, thereafter building up very gradually to an end-point of maximal improvement with the minimum of side effects. In many patients 2–3 mg daily is adequate for symptom relief, but sometimes much larger doses are required. Dosage can often later be reduced over several months or years without loss of benefit, sometimes to very low levels. Pimozide is effective in many patients and is often less sedating, likewise sulpiride which is less prone to provoke extrapyramidal disturbance. Haloperidol and pimozide are both licensed by the Food and Drug Administration in the USA for the treatment of Tourette's. Sallee *et al.* (1997) suggest that pimozide may be preferable. A number of small studies show promising results for atypical antipsychotic drugs such as ziprasidone (Sallee *et al.* 2000, 2003), olanzapine (Budman *et al.* 2001; Stephens *et al.* 2004) and quetiapine (Mukaddes & Abali 2003). Risperidone was effective in two randomised controlled trials (Dion *et al.* 2002; Gaffney *et al.* 2002), although may be associated with weight gain or dysphoria (Margoless *et al.* 2002). Centrally active α -adrenergic agonists such as clonidine or guanfacine, have also been shown to be effective in several randomised controlled trials (Leckman *et al.* 1991; Tourette's Syndrome Study Group 2002). However, differences in response by individual patients may indicate a trial of several different agents. The anticonvulsant clonazepam and the antidepressant clomipramine have also occasionally shown success, likewise calcium channel blockers such as nifedipine and verapamil. Documented responses have been reported with naloxone, lithium carbonate, tetrabenazine and fluvoxamine (Robertson 1989; Kurlan & Trinidad 1995). Although dopamine receptor antagonists have proven efficacy, dopamine agonists such as pergolide (Gilbert *et al.* 2003) and ropinirole

(Anca *et al.* 2004) also appear beneficial. It is believed that they are acting at presynaptic rather than postsynaptic receptors in the striatum or the cortex. Hoopes (1999) reported the successful use of donepezil, whilst Muller-Vahl (2003) described improvement in a single patient following the administration of Δ^9 -tetrahydrocannabinol. Other currently experimental drug regimens are described in the comprehensive review by Jimenez-Jimenez and Garcia-Ruiz (2001).

Leckman (2002) advises treating comorbid obsessive-compulsive symptoms and ADHD prior to treating the tic disorder. Obsessive-compulsive disorders are typically treated with serotonergic drugs such as clomipramine or SSRIs. Scahill *et al.* (1997) reported that tic frequency was not increased with the use of fluoxetine. Management of ADHD is most effective with stimulant drugs such as dexamfetamine or methylphenidate. There is now consistent evidence that the use of stimulants does not worsen tic behaviour (Gadow *et al.* 1999; Tourette's Syndrome Study Group 2002).

Porta *et al.* (2004) treated 30 patients with vocal cord injections of botulinum toxin. They showed that not only could this be effective for vocal tic and coprolalia but reports of the preceding sensory phenomena declined and overall quality of life improved. Operative intervention by way of stereotactic surgery to the dentate nucleus of the cerebellum, or the rostral intralaminar and medial thalamic nuclei, has been found to help occasional patients (Hassler & Dieckmann 1970, 1973; Nadvornik *et al.* 1972). Vandewalle *et al.* (1999) showed that tics could be reduced with high-frequency stimulation of the nucleus ventralis oralis of the internal thalamus. Even in severely affected patients much can often be achieved by careful adjustment of drug regimens and proper attention to psychosocial aspects of management. Valuable support and information can be provided to patients by the Tourette Syndrome Associations in both the UK and the USA.

Psychogenic movement disorder

Approximately one-third of patients referred to a general neurology clinic have symptoms that are at best only partially explained by organic disease (Carson *et al.* 2000). Follow-up studies have demonstrated that less than 5% of these patients will subsequently be found to have an underlying medical condition that was initially missed (Couprie *et al.* 1995; Crimlisk *et al.* 1998; Carson *et al.* 2003). Movement disorder is a relatively unusual presentation in this context, but in specialist movement disorder clinics 5% of patients may be diagnosed as having a disorder that has no basis in medical disease (Factor *et al.* 1995b; Thomas & Jankovic 2004). There is some suggestion in the literature that this figure may be an underestimate: Thomas and Jankovic (2004) present evidence that the rate at which this diagnosis is made is increasing exponentially, a fact they attribute to a

better understanding of the spectrum of organic movement disorders among both general and specialist neurologists. There is also a grey area between syndromes that are demonstrably organic and those regarded as psychogenic, for example the syndrome of fixed dystonia (Schrag *et al.* 2004) (see below) and the closely related problem of post-traumatic dystonia. Without simple diagnostic tests, debate will continue about the nature of such syndromes but it seems likely that in some cases prevailing views about aetiology stand to be revised in favour of the psychogenic.

The neurological literature has retained the term 'psychogenic movement disorders' to describe this group of conditions. In the absence of a clear consensus about suitable alternatives, this term will be adopted here. However, it should be recognised that this term groups together the different categories of psychiatric disorder that may present with somatic symptoms or signs, namely conversion or somatoform disorder and factitious disorder. In clinical practice, having decided that a patient's movement disorder cannot be attributed to organic disease, reaching a psychiatric diagnosis requires judgements to be made in two stages. Firstly, the clinician must decide whether the symptoms are generated unconsciously or consciously. If unconscious, the diagnosis is one of conversion (somatoform) disorder. Secondly, if the symptoms are judged to be wilfully feigned, the clinician must decide why the patient is simulating illness: if the motive is thought to be understandable primarily in terms of psychological needs (to adopt the sick role), the diagnosis is one of factitious disorder; if the motives appear to be purely practical (e.g. to avoid a criminal conviction or for some obvious financial gain), the term 'malingering' (not a medical diagnosis as such) is used. In practice the distinction between factitious disorder and malingering is often difficult to make, let alone the distinction between unconscious and conscious symptom generation, and both dichotomies are undoubtedly better conceived of as dimensions. The area remains controversial and the final diagnosis will be influenced as much by the clinician's opinions about this area in general as by any objective evidence gleaned during clinical assessment.

Clinical features

Using diagnostic criteria proposed by Fahn and Williams (1988) (Table 12.2), several series of patients with psychogenic movement disorder (PMD) have been described (Factor *et al.* 1995b; Williams *et al.* 1995; Feinstein *et al.* 2001). Patients, two-thirds of whom are female, tend to present in their early forties. Tremor is the most common symptom (accounting for around 40% of patients), closely followed by dystonia (in around one-third) (Lang 2006). Gait disorder, myoclonus and psychogenic parkinsonism are less common. No single clinical feature allows the diagnosis to be made with certainty. Rather it is a deviation from the typical clini-

Table 12.2 Diagnostic criteria for psychogenic movement disorder. (From Fahn & Williams 1988)

Degree of diagnostic certainty	Criteria
Documented*	Persistent relief by psychotherapy, suggestion or placebo; or observed without the movement disorder when the patient believed himself to be unobserved
Clinically established*	Incongruent with classical movement disorder or inconsistent over time, plus at least one of the following: other psychogenic signs; multiple somatisations; or an obvious psychiatric disturbance
Probable	Incongruent or inconsistent over time as above, or psychogenic signs or multiple somatisations
Possible	Evidence of emotional disturbance

*The first two categories have subsequently been amalgamated to comprise a clinically definite category (Williams *et al.* 1995).

cal profile of any of the recognised organic syndromes that raises the possibility of PMD (Schrag & Lang 2005). Thus, the diagnosis is best made by a neurologist with experience in movement disorders. The most important features on history that favour a diagnosis of PMD include abrupt onset, rapid progression to maximal severity and inconsistencies over time (in particular a history of variable movement disorders migrating between different parts of the body). A history of previous medically unexplained symptoms is highly suggestive. On examination (Table 12.3), particular attention should be paid to the consistency of abnormal movements, whether the disorder is modified by attention or distraction, and the presence of other non-physiological abnormalities such as functional weakness or sensory complaints.

The 'gold standard' diagnostic criterion for PMD is widely regarded to be the demonstration of persistent relief following psychotherapy, suggestion or placebo. However, organic cases may occasionally demonstrate some of these characteristics (Thomas & Jankovic 2004). Cervical dystonia, for example, may be associated with transient remission in as many as 25% which, if it were to coincide with psychotherapy, could lead to misdiagnosis. Psychogenic disorders may be associated with the secondary physical consequences of prolonged immobility, or the maintenance of abnormal postures. For example, contractures are seen in psychogenic fixed dystonia that can account for persistence of abnormal postures in sleep and under anaesthesia.

An exception to the general rule that variability over time points to a psychogenic aetiology concerns the syndrome of fixed dystonia, which deserves special consideration. Idiopathic or primary dystonia typically displays some variation over time, including being triggered by activity or specific tasks (e.g. writing), and temporary relief by sensory

tricks (*geste antagoniste*). In contrast, fixed dystonia, as its name implies, is relatively constant. In a careful investigation of a series of patients with fixed dystonias, Schrag *et al.* (2004) demonstrated compelling evidence of a psychogenic aetiology in the majority of cases. From a series of 103 patients with fixed dystonia, 41 were investigated prospectively. Detailed neuropsychiatric assessment was conducted in a subgroup of 26 who were compared with a control group of 20 patients with classical dystonia. In the prospective group, 37% met criteria for clinically definite PMD and 29% for somatisation disorder. The authors considered both figures to be underestimates and in the prospectively examined group found only 10% in whom there was no suggestion of a psychogenic disorder. In comparison with the control group patients with fixed dystonia had higher rates of dissociative and affective disorders. The onset of fixed dystonia occurred after a peripheral injury in 68% of cases (compared with 5% in the control group) and 44% of patients had associated features of complex regional pain syndrome (reflex sympathetic dystrophy). The authors conclude that fixed dystonia commonly occurs after peripheral injury and overlaps with complex regional pain syndrome. The study provides compelling evidence that this syndrome has a psychogenic basis in the majority of patients.

The presence of a psychiatric history is often cited as evidence in favour of a psychogenic origin for the presenting movement disorder. However, caution is clearly required as many organic movement disorders are associated with high rates of psychiatric comorbidity and in some, Huntington's disease for example, psychiatric and behavioural problems may develop long before more obvious neurological features. However, patients with PMD do have very high rates of psychiatric disorder. Feinstein *et al.* (2001) have reported the prevalence of psychiatric disorders defined using DSM-

Table 12.3 Examination procedures in psychogenic movement disorders.* (From Stone *et al.* 2005a.)

Disorder	Feature	Examination procedure	Specific caveat
Tremor	Variability	Observe for spontaneous variability in frequency, amplitude or distribution	All movement disorders vary to some degree and will often worsen with anxiety
	Distraction	Observe for improvement while the patient performs a distraction task. Distraction tasks include asking the patient to perform tests of mental concentration (e.g. serial subtraction) or physical tasks with his normal limbs (e.g. rapid alternating hand movements)	Organic disorders may be susceptible to attentional factors to a minor degree
	Entrainment	The patient is asked to make a rhythmical movement with his normal hand or foot. In psychogenic tremor the normal limb either 'entrains' to the same rhythm as the abnormal side, or the requested rhythm becomes irregular or incomplete. A slower (3 Hz) rhythm may be a more sensitive test than faster rhythms	
	Coactivation	A load (weight or pressure) is applied to the affected limb. Organic tremor tends to diminish whereas functional tremor may increase in amplitude. This may be because of coactivation of agonist and antagonist muscle groups. In this situation increased load triggers physiological clonus	
Dystonia	Distraction	As above	
Myoclonus	Variability in stimulus response	Psychogenic myoclonus may be triggered by a variety of stimuli (e.g. noise, light or eliciting tendon reflexes). Observe for variability in the delay between stimulus and jerk. The delay is also usually longer than seen in stimulus-sensitive organic myoclonus	

*In each case a negative test does not exclude a psychogenic basis for the disorder. As with any clinical examination, the usefulness of these tests will depend on the clinician's experience in applying these procedures to patients with both organic and psychogenic disorders.

IV criteria in a series of 42 patients with PMD. The lifetime prevalence rates for the most common comorbid diagnoses were 43% for major depression, 38% for anxiety disorders, and 28.6% for mixed major depression and anxiety. Personality disorders were identified in 45%, and 38% had prominent features of other medically unexplained symptoms.

Investigations

Functional imaging with ^{123}I -2 β -carboxymethoxy-3- β -(4-iodophenyl)-tropane and SPECT may be helpful in confirming a diagnosis of Parkinson's disease, with over 90% of patients having abnormal scans early in the course of the disease (Jennings *et al.* 2004). A very high specificity for this technique has also been reported but studies involving substantial numbers of patients with PMD are required before the utility of this procedure can truly be gauged. Almost all reporting of scans is currently based on qualitative assessment and in clinical settings the extent of false negatives and positives will undoubtedly vary between centres.

Electromyography can be used to verify some of the characteristics of psychogenic tremor and myoclonus listed in Table 12.3, including variability in tremor frequency, coactivation, entrainment and prolonged latency (>75 ms) in psychogenic myoclonus (Schrag & Lang 2005). However, the sensitivity and specificity of these techniques has yet to be established. Combined electroencephalographic and electromyographic recordings may be helpful in assessing myoclonus. The demonstration of a prolonged pre-movement Bereitschaftspotential is good evidence of a psychogenic basis but this may be attenuated or even absent in healthy subjects under certain conditions (Terada *et al.* 1995). Furthermore, this technique requires back-averaging of multiple events, which may be impractical if the jerks occur infrequently. A pathological 4–7 Hz drive to peripheral muscles has recently been demonstrated in patients with DYT1 dystonia (Grosse *et al.* 2004). This finding was present in 10 of 12 patients with this disorder but not in healthy controls or patients with PMD. However, the specificity and sensitivity of this abnormality is unknown.

Aetiology

No studies have specifically sought to identify putative aetiological factors in PMD. However, there is considerable overlap between different somatoform presentations (Wessely *et al.* 1999) and it is reasonable to assume that the biological, psychological and social factors that may act to predispose, trigger and maintain other somatoform disorders also operate in PMD (Stone *et al.* 2005b). Onset after minor physical injury is common and much more frequently reported than onset after a psychological trauma (Factor *et al.* 1995b; Feinstein *et al.* 2001; Schrag *et al.* 2004).

The physiological mechanisms by which PMDs might be maintained have received little attention. Raethjen *et al.* (2004) have proposed two alternative mechanisms that might underlie psychogenic tremor. In the first, the movements are essentially construed simply as arising from voluntary-like activity. The second mechanism involves co-contraction of normally opposing agonist/antagonist muscle groups. In this case tremor arises through physiological clonus, as seen in shivering or with prolonged tonic muscular exertion.

Management and prognosis

There have been no controlled treatment trials in PMD and few detailed outcome studies. Factor *et al.* (1995b) reported resolution of symptoms in 35% of 28 patients over a 6-year period. Williams *et al.* (1995) describe outcome in 25 patients who participated in an intensive treatment programme combining psychotherapy in all cases with family sessions (58%), hypnosis (42%) and placebo therapy (13%). Antidepressants were prescribed in 71%. An impressive 52% were felt to have benefited significantly from treatment, with complete resolution of symptoms in 25%; 35% of patients returned to employment. A less optimistic view comes from the most detailed study to date by Feinstein *et al.* (2001). These authors describe outcome in 42 patients (from a series of 88) followed up after a mean interval of 3.2 years from initial assessment. The PMD had remitted in only four patients and in two of these had been replaced by a different mental disorder. Symptoms had improved in one-third of the patients but were the same or worse in over half. Poor outcome was associated with long duration of symptoms at initial presentation, gradual onset and by the presence of psychiatric comorbidity. This was a naturalistic outcome study and treatment given, if any, was not described. These findings are broadly similar to those of recent studies of long-term prognosis in other motor somatoform disorders; if anything, they suggest that PMD may carry a particularly poor prognosis. Thus, Crimlisk *et al.* (1998) report resolution of the presenting symptom in 28% of 64 patients (half of whom had a PMD) followed over 6 years. In a study of functional motor and sensory symptoms in 47 patients, Stone

et al. (2003) found that 83% reported significant somatic symptoms after a mean follow-up period of 12.5 years. These authors commented on a strong tendency for initial symptoms to be replaced or joined by new ones.

There is little evidence on which to base any specific recommendations for treatment in PMD. Principles and techniques that have proven useful in other somatoform conditions are likely to be of benefit, although many have yet to be fully evaluated. A careful explanation of the diagnosis is of paramount importance (Stone *et al.* 2005b). Psychiatric assessment should include detailed enquiry into the patient's psychosocial background, aiming in particular to identify significant maintaining factors that might otherwise be barriers to recovery. Antidepressant medication may be helpful, even in the absence of significant depression or anxiety (O'Malley *et al.* 1999). Cognitive behavioural therapy is a well-established treatment for a variety of somatoform disorders (Kroenke & Swindle 2000), but other forms of psychotherapy may be preferable for some patients. A multidisciplinary approach combining psychotherapy with physiotherapy and other rehabilitation services has been recommended but again requires evaluation (Schrag *et al.* 2004).

Sleep Disorders

Meryl Dahlitz and Michael D. Kopelman

Institute of Psychiatry, King's College, London

Normal sleep

No one knows what sleep is for. However, our waking performance, vigilance and vigour, our health and happiness and the quality of our waking lives are profoundly affected by the way we sleep. Some of these features can be measured but others, such as peace of mind and feeling refreshed, cannot. One of the most important functions of sleep, as shown by the prominence of sleep in the young of all species, may be the promotion of brain development. Sleep and waking occur about the same time every day and an important characteristic of sleep is its strong circadian rhythmicity (Fig. 13.1) (Parkes 1985). Although the body has a capacity to make up recent sleep loss, there appears to be no capacity to recuperate from ancient or chronic sleep deprivation. Despite some recent advances, much of the normal physiology of sleep, its anatomical basis and the neurotransmitters involved remain unexplained.

Many laboratories have demonstrated that sleep is not a passive event but an active physiological process, with clearly defined electrocorticographic and behavioural changes, and which depends on specific neurochemical mechanisms and activity of brainstem nuclei and areas extending from the medulla to the posterior diencephalon. The hypothalamus was recognized as a regulator of sleep and wakefulness with the encephalitis lethargica epidemic of 1917–24, when individuals developed major sleep abnormalities and were found to have hypothalamic lesions at post-mortem (Von Economo 1931). The sleep control systems of the hypothalamus interact with the circadian pacemaker in the suprachiasmatic nucleus as well as interacting with other hypothalamic functions such as the regulation of food intake, metabolism, hormone release and core temperature regulation (Mignot *et al.* 2002a). The finding that hypothalamic pathology is associated with aspects of motor control in narcolepsy has led to the hypothesis that the hypothalamus

also plays a role in facilitating motor activity tonically and phasically in association with motivated behaviours (Siegel 2004), as well as in the normal atonia of sleep (see below). Animal models of narcolepsy have demonstrated involvement of the hypothalamic neuropeptide hypocretin (also called orexin) in sleep mechanisms. The hypocretin system encompasses two peptides, hypocretin-1 (orexin A) and hypocretin-2 (orexin B), that are both cleaved from a precursor molecule, preprohypocretin, produced by a small number (about 50 000) of specialised cells located in the lateral and perifornical regions of the hypothalamus. Hypocretin neurones have widespread connections throughout the body. The hypocretin system directly and strongly innervates and potently excites noradrenergic, dopaminergic, serotonergic, histaminergic and cholinergic neurones. Hypocretin also has a major role in modulating the release of glutamate and other amino acid transmitters. There is evidence that the arousal effect of hypocretin-1 depends on the activation of histaminergic neurotransmission mediated by the H_1 histamine receptor (Huang *et al.* 2001). Behavioural investigations in animals have revealed that hypocretin is released at high levels in waking especially during periods of increased motor activity and also in rapid eye movement (REM) sleep and at minimal levels in non-REM (NREM) sleep (Siegel 2004). Hypocretin activity may be critical in opposing sleep propensity during periods of prolonged wakefulness (Yoshida *et al.* 2001). There are two known receptors, *hcrt1r-1* and *hcrt1r-2*, with differential affinity for the two ligands.

Regular cycles of sleep and wakefulness are determined by external factors (zeitgebers) and internal oscillators or biochemical clocks. When separated from all external time cues most humans have a daily sleep–wake cycle and also a temperature cycle time nearer to 25 than 24 hours. More than 100 biological functions vary between maximum and minimum levels over a 24-hour period. Many different

Fig. 13.1 Circadian rhythms in sleep. (Reprinted from Czeisler, C.A. & Richardson, G.S. Circadian timekeeping in health and disease. Part 1. Basic properties of circadian timekeepers. *New England Journal of Medicine* (1983) **309**, 469–476, with permission from Moore-Ede *et al.*)

genetically coded circadian oscillators have been discovered throughout the body but the control of sleep–wake timing appears to be orchestrated by the paired suprachiasmatic nuclei of the hypothalamus. The sensitivity of circadian timekeeping and sleep–wake alternation is exquisite. The phase relationships of oscillatory processes during entrainment to the 24-hour day is timed to facilitate the ability to maintain a consolidated episode of sleep at night (Dijk &

Czeisler 1994). Minor variations in the duration of sleep–wake cycles are corrected within the next and, to a smaller amount, the next but one cycle and a complete phase reversal due to a 12-hour time zone shift can normally be accommodated within a few days. However, adjustment to night shift-work takes longer than recovery from jet-lag and although symptoms usually improve after a week, long-term night-workers often have persistent sleep abnormalities. Although

Fig. 13.2 Typical pattern of sleep in a young adult. Sleep stages are shown here during an 8-hour night. The subject enters sleep from wakefulness through Stage 1 and enters progressively deeper sleep stages. The cyclical pattern of progression through sleep stages is evident. REM sleep does not occur until more than 1 hour after sleep

onset. REM episodes become more prevalent during the sleep period and are particularly evident in the last third of the night. Brief arousals into wakefulness are common after REM episodes. One is shown here just before the fourth hour of sleep.

adaptation to shiftwork depends on many factors, the most important are the pattern of the shiftwork and the regularity or irregularity of the work schedule. Rotating shiftwork patterns are much more disruptive than fixed shift changes and non-24-hour cycles are particularly difficult. Rotating shifts cause less disturbance to sleep if they progressively phase delay rather than phase advance. There is considerable individual variation in the capacity to synchronise to external time cues (entrain) but generally young people adapt much better than old, with the greatest deterioration in the fourth decade. Normal sleep habits play a large part in determining ability to adapt to shiftwork. People who spontaneously wake early, 'larks' on the Horne and Ostberg (1976) scale, generally have less variable sleep and awakening times and less capacity to adapt to shiftwork than 'owls'.

Different behavioural forms of sleep were described by Macnish (1830) but the concurrent brain electrical changes were not clearly recognised until the development of the electroencephalogram (EEG). Loomis *et al.* (1935) identified five different patterns of electrical activity in the brain that formed the basis for all subsequent classifications of sleep stages. In 1953, Aserinski and Kleitman identified periodic bursts of eye movement during sleep that were different from the slow rolling eye movements that accompany sleep onset. These periodic eye movements were associated with dreaming by Dement and Kleitman (1957). This state of sleep is now commonly known as REM sleep.

Three basic parameters are required to define sleep stage: EEG, electro-oculogram and electromyogram. With regard to EEG, sleep is composed of four NREM stages and one REM stage. The two very different kinds of sleep alternate in

regular cycles (Fig. 13.2). In addition to characteristic variations in spontaneous activity of the brain, there are also changes in evoked activity with sensory stimulation. During both wakefulness and sleep, spontaneous EEG activity can be divided into four frequency bands: beta (>12 Hz), alpha (8–12 Hz), theta (4–8 Hz) and delta (1–3 Hz). The amplitude of these waves is generally greater for slow than for fast frequencies, partly because of a filter effect of the skull and scalp. At sleep onset, the alpha rhythm of relaxed wakefulness gradually reduces in frequency, waxing and waning and eventually giving way to a low-voltage irregular pattern characteristic of stage 1 NREM sleep. The rapid eye movements of wakefulness give way to slow rolling or horizontal eye movements.

Stage 1 NREM sleep lasts about 30 seconds to 7 minutes. If aroused, subjects usually report being half-awake. Three characteristic patterns emerge on the EEG of stage 2 NREM sleep: sleep spindles, vertex sharp waves and K potentials. Sleep spindles are so called because the waves at the start and the end of brief bursts of activity of 12–15 Hz are of lower amplitude than the waves in the middle, thereby resembling a spindle shape. Sleep spindles are present in NREM stages 2, 3 and 4. However, since they are superimposed on large-amplitude slow waves in NREM stages 3 and 4, they are difficult to see with the naked eye. About five spindles occur each minute in stage 2 and some are associated with K complexes. K complexes appear to be non-specific evoked potentials characteristic of NREM sleep, and combine a frontal slow wave, a central spindle and a vertex sharp wave. On the EEG, they appear as an initial negative wave followed 0.75 seconds later by a positive wave simultaneously over all areas of the

head. Although many K complexes appear to be spontaneous, some are responses to external stimuli and others are provoked by internal autonomic activity such as gut and bladder contractions. Between two and three K complexes occur each minute. Stage 3 NREM sleep is characterised by a continuous increase in EEG voltage and a decrease in frequency. With the increase in voltage the EEG patterns become more synchronised. As the sleeper moves from NREM stage 3 to NREM stage 4 sleep, the EEG becomes increasingly dominated by slow delta waves. Stage 3 sleep is relatively stable across different age groups but the high abundance of slow waves characteristic of stage 4 is typical of sleep in young people. The proportion of stage 4 rapidly diminishes with age so that there is little or none left by the age of 60.

There is a progressive increase in the stimulus threshold necessary to produce arousal through NREM stages 1 to 4. Noise stimuli that are subthreshold for arousal may not cause any alteration in the EEG. NREM stages 3 and 4 occur within 30–45 minutes in healthy young adults and last from a few minutes to an hour. Usually, NREM stage 4 is followed by a brief episode of stage 2 NREM before the first REM period.

The first REM period of the night usually commences 75–90 minutes after sleep onset, and REM periods alternate with NREM periods at about 90-minute intervals during a normal night's sleep. The duration of REM episodes increases with each sleep cycle, the first lasting between 5 and 10 minutes and the fourth and fifth REM episodes lasting 20–60 minutes. The intensity of REM episodes in terms of physiological manifestations, frequency of eye movements and respiratory irregularity, and in the intensity of dreams, also increases during the night. In contrast, NREM stages 3 and 4 are progressively lost, with less NREM stages 3–4 in the second than in the first cycle, and often no NREM stages 3–4 at all in the late cycles (see Fig. 13.3).

Sleep disorders

Sleep disorders are increasingly recognised and are associated with significant morbidity (Kryger *et al.* 2000). There are four main categories of sleep disorder in recent classification: dyssomnias, parasomnias, medical/psychiatric sleep disorders, and proposed sleep disorders. Although the term

Fig. 13.3 Behavioural states in humans. States of waking, NREM sleep and REM sleep have behavioural, polygraphic and psychological manifestations. In the row labelled behaviour, changes in position (detectable by time-lapse photography or video) can occur during waking and in concert with phase changes of the sleep cycle. Two different mechanisms account for sleep immobility. The first is disfacilitation (during stages I–IV of NREM sleep). The second is inhibition (during REM sleep). During dreams, we imagine that we move, but we do not. Sample tracings of three variables used to

distinguish the state are shown: an electromyogram (EMG), an electroencephalogram (EEG) and electro-oculogram (EOG). The EMG tracings are highest during waking, intermediate during NREM sleep and lowest during REM sleep. The EEG and EOG are both activated during waking and inactivated during NREM sleep. Each sample shown is approximately 20 seconds long. The three bottom rows describe other subjective and objective state variables. From J Allan Hobson (2005) *Sleep is of the brain, by the brain and for the brain*. *Nature* **437**, 1254–1256.

'dyssomnia' was previously applied to any disorder of sleep or wakefulness, it is now confined to the primary sleep disorders. Dyssomnias produce insomnia and/or excessive sleepiness and without these symptoms the dyssomnias would not exist. The dyssomnias are divided into three groups: intrinsic sleep disorders, extrinsic sleep disorders and circadian rhythm disorders.

The international classification of sleep disorders is based on assumptions about the pathophysiology of the disorders and may seem arbitrary at first glance. For example, post-traumatic hypersomnia would not exist without the external event that produced the head injury. However, because the hypersomnia appears to be of central nervous system (CNS) origin and persists after the traumatic event, it is classified as an intrinsic sleep disorder. Similarly, an adjustment sleep disorder is due to psychological factors and so could be considered to be internally generated. However, an external event is the cause and if removed the sleep disorder resolves. Consequently, this is classified as an extrinsic sleep disorder.

Intrinsic dyssomnias: insomnia

Insomnia is a subjective phenomenon of difficulty falling asleep, repeated waking and/or early-morning arousal. Also patients may report not feeling refreshed by sleep. Insomnia is difficult to verify objectively and there is often little correlation between the report of sleeplessness and laboratory recordings of sleep. Psychological factors contribute to insomnia in up to 80% of cases (Nicholson & Marks 1983). Nevertheless, people who do complain of insomnia mostly sleep worse than controls, sleep less, and wake up in the night more often (Frankel *et al.* 1976). It is unknown whether some people need more sleep, or sleep of a different pattern from that which they habitually obtain. Some subjects, who have very disturbed sleep whilst in the sleep laboratory, do not complain about either sleeping or waking. Sleep laboratory investigations rarely reveal a cause but a diagnosis may be reached by taking a careful clinical history.

The complaint of insomnia is far more common than any other complaint about sleep. Questionnaire surveys show that up to one-third of the general population experiences sleeplessness, although the prevalence varies from country to country. Family practice surveys show that far fewer complain to their doctors about insomnia than experience sleeplessness from time to time. About 3% of the population take hypnotic medication at least occasionally. Overall, women complain twice as often about their sleep as men, and housewives are particularly bad sleepers. Insomnia is frequently associated with depression, mania, anxiety, anorexia nervosa, obsessive-compulsive neurosis and schizophrenia. In normal subjects, insomnia may be caused by stress, such as bereavement, examinations or sickness. Kales and Kales (1983) showed that the complaint of insomnia was most common in subjects from lower socioeconomic

groups and of poor education. Unsurprisingly, both heavy drinkers and heavy smokers describe themselves as sleeping less than non-drinkers and non-smokers. Paradoxically, oversleeping for long periods or merely staying in bed can lead to a feeling of poor sleep and sometimes the complaint of insomnia.

The frequency and severity of insomnia increase with age in both sexes. In the normal population, periods of waking during the night become increasingly common with age. Total sleep time decreases from an average of 8 hours daily in young adulthood to about 6 hours daily at age 90. This is accompanied by more nocturnal arousals. These changes begin in early adulthood: 30-year-olds have only half as much stage 4 NREM as 20 year olds and experience twice as much nocturnal wakefulness. In comparison the proportion of REM sleep remains relatively constant, at about 22% of total sleep time, but the preservation of REM sleep in the elderly correlates with the preservation of intelligence. There is much less REM sleep time amongst the elderly demented. The causes of insomnia in the elderly include medical disorders, pain, psychological and social factors, absence of regular activities, minimal exercise, daytime naps, and worries about health, money and/or ultimate destiny. Sleep apnoea and sleep myoclonus, both of which are increasingly prevalent with age, may present as insomnia in some cases. However, the normal deterioration of sleep processes with age may be responsible for much insomnia experienced in the elderly (Regelstein 1980). There is much evidence that the ubiquitous overuse of sedative medication in the elderly is harmful. Daytime sedation, agitation, confusion and disturbed behaviour may disappear when the sedatives are stopped. Sleep apnoea, present in up to 50% of people over 65, is exacerbated by hypnotics (Guilleminault *et al.* 1978). In patients with dementia, who often experience an exaggeration of the normal age-related changes in sleep and are often confused and restless at night, sedatives can be particularly unhelpful and can cause paroxysmal rage and exacerbate behavioural disturbance.

Common observation shows that the more deeply one sleeps, the more alert one is when awake but this is surprisingly difficult to quantify. Initiation and motivation may suffer after a poor night's sleep, although there may be no deterioration in simple motor or memory tasks. The major effect of insomnia in patients is to cause sleepiness, fatigue, lack of concentration, and sometimes muscle-aching and mild depression, similar to the effects of sleep deprivation experiments in healthy young adults.

In those who regularly sleep for only short periods, the mortality rate is surprisingly high (Kripke *et al.* 1979; Kripke *et al.* 1983). Medical conditions inducing insomnia and leading to the taking of sleeping pills would be expected to produce a high death rate. Amongst those who sleep only 6 hours or less, there is a high mortality rate for ischaemic heart disease, stroke and cancer (Wingard 1983). The relative

mortality rate of short sleepers was 1.3 times that of normal sleepers when correction was made for age, sex, race, socioeconomic status, physical health, weight, smoking and alcohol consumption.

Much information can be derived from a consideration of the pattern of the insomnia. Difficulty falling asleep, with a sleep latency greater than 30 minutes, is usually related to anxiety, depression, bereavement, accident, environmental stimuli or drugs. The high level of arousal that prevents sleep onset may be associated with high plasma noradrenaline (norepinephrine) levels. High noradrenaline levels may also explain the insomnia of physiological starvation. Sleep maintenance insomnia, with frequent arousals, has many causes. Drugs, particularly alcohol or daytime stimulants, and hypnotic withdrawal should be considered. Medical and psychiatric illness, parasomnias, sleep apnoea, restless legs and sleep myoclonus are also common causes. Frequent arousals at 90-minute intervals are almost always due to REM sleep nightmares. Awakenings from REM sleep are also characteristic of cluster headaches. Random arousals from both REM and NREM sleep are typical of sleep apnoea and anxiety. Early-morning awakening without further sleeping is characteristic of both depression and hypomania, although it may occur with any kind of excitement. Phase-shift disorders can masquerade as insomnia; however, despite unusual sleep onset times, sleep is normal in duration. Cyclical insomnia can be due to recurrent unipolar or bipolar depression, or occasionally menstrual or endocrine disorders.

The history of the insomnia is also helpful diagnostically. Transient insomnia is experienced by everyone several times during their lives and has many causes, including stress, illness, childbirth, drugs, emotional crisis and jet-lag. The patient may experience sleep-onset insomnia, maintenance insomnia or premature awakening. Regardless of form, transient insomnia recovers within 2–4 weeks.

In contrast, chronic insomnia may be lifelong. Idiopathic chronic insomnia accounts for up to one-quarter of all cases of chronic insomnia. It begins early in life with fragmented short sleep episodes and persists as fitful sleep of only 3–4 hours at night in adulthood with early waking and insomnia by day as well as by night. Patients complain of fatigue, irritability and symptoms of somatic depression. It is sometimes familial. Occasionally there are signs of minimal brain damage, dyslexia or hyperkinesia and there may be minor EEG abnormalities during sleep. Clinically, idiopathic insomnia may be impossible to differentiate from chronic psychophysiological insomnia when it presents in adulthood. Both conditions are difficult to treat successfully using drugs, conditioning or biofeedback. Relaxation therapy may be helpful in a proportion of patients.

Most chronic insomnias are secondary to an obvious medical, psychiatric or behavioural problem. Common neurological causes of insomnia include head injury, infection, parkinsonism, encephalitis, psychomotor and general-

ised seizures, cortical and subcortical lesions, spinal cord damage, cerebrovascular disease and dementia. Insomnia in neurological disorders may be the result of (i) primary involvement of sleep mechanisms, for example in progressive supranuclear palsy; (ii) abnormal sensory mechanisms, for example in spinal cord lesions; or (iii) stress, discomfort and pain as with nerve or root compression, disc lesions, night cramps or fibrositis. Common medical causes of night waking due to pain include ulcer pain, nocturnal angina, nocturnal asthma and chronic or intermittent airflow obstruction. Metabolic diseases can disturb sleep by affecting sleep mechanisms. Chronic renal insufficiency causes short, fragmented, disorganised sleep. Following dialysis or transplantation, sleep may improve but it rarely becomes normal. Poor sleep in uraemia has been attributed to irreversible neuronal damage but is more likely to be the result of metabolic disturbance. Hyperthyroidism can cause fragmented short sleep with excessive delta activity; hypothyroidism causes excessive sleepiness with lack of delta activity and obstructive sleep apnoea. Following return to the euthyroid condition, sleep can be slow to recover, taking up to 1 year to become normal. Up to one-quarter of acromegals develop disturbed sleep due to obstructive sleep apnoea. Hypogonadism and menopause can also cause insomnia.

Psychiatric illness frequently causes a greater degree of sleep disturbance than any other cause of insomnia. Severe depression is usually accompanied by difficulty staying asleep and early-morning arousal, but often without delay in sleep onset, whereas in mania the onset of sleep is delayed and sleep is short. Most patients with bipolar illness sleep more when they are depressed and less when they are manic. During the switch from depression to mania, several days may pass without sleep. Sleep is always shortened in mild manic disorder (hypomania) and gravely disturbed in severe mania. There is more variation in the pattern of sleep disturbance in depression; some depressed patients sleep for excessively long not short periods, whilst others have apparently normal sleep. Patients often find that their sleep is unrefreshing. Sleep disturbance is often the first symptom of depression, and restoration of sleep may be the first sign of recovery. The sleep pattern in obsessive-compulsive neurosis is similar to that found in depression, with poor sleep and frequent awakenings, short sleep time, short REM latency and little stage 4 NREM. As in depression, some patients develop hypersomnia.

Anxiety characteristically causes sleep-onset insomnia. Ruminations may maintain a level of arousal that prevents sleep onset. Sleep disturbance as the result of anxiety is more common in young people than in the elderly. Many patients with insomnia dread a further bad night's sleep. This may result in fear and panic, increased arousal and a self-fulfilling prophecy. A phobia of sleepless nights may develop. Relaxation and behaviour therapy may be helpful

to these patients. Schizophrenia may be accompanied by severe sleep disturbance, but the sleep pattern in chronic schizophrenia is usually normal and with a normal proportion of REM.

Drugs are a common cause of chronic insomnia. Alcohol can have a profound effect on sleep, and sleep may be totally abolished during heavy binges. More moderate doses of alcohol shorten sleep latency but cause subsequent sleep disruption. Intoxication causes an increase in delta sleep and a decrease with withdrawal. There is a marked but variable decrease in slow-wave sleep following alcohol withdrawal, perhaps related to different levels of tolerance. There is a dose-dependent depression of REM sleep with a compensatory increase on withdrawal. Depending on the alcohol dose, the compensatory REM sleep rebound on withdrawal may occur on the same night or on the following night. Delirium tremens is closely correlated with increased REM time, and some of the agitation in delirium tremens may be caused by REM breakthrough into wakefulness. Chronic alcoholics have fragmented sleep, with little or no delta sleep, decreased REM sleep and many arousals. The sleep-wake cycle becomes disrupted, with excessive daytime sleepiness and frequent naps. Normal motor inhibition of REM sleep may be lost and electromyographic activity during REM is increased not decreased. The sleep of alcoholics can remain disturbed for as long as 2 years after alcohol withdrawal, with difficulty falling asleep, frequent arousals and reduced delta sleep. Sleep changes, particularly loss of REM sleep and alcohol-provoked sleep apnoea, may contribute to memory impairment in chronic alcoholics.

Caffeine, mainly from coffee, tea, cola and chocolate, is another common cause of sleep disruption. The caffeine dose in four cups of coffee at bedtime will cause a marked increase in nocturnal arousals in normal subjects. Caffeine increases arousals even in people who claim to be unaffected by it.

The acute administration of a short half-life hypnotic may cause early-morning rebound insomnia and anxiety, not sedation, the morning after. Withdrawal from chronic use of short-acting hypnotic drugs can lead to a temporary insomnia of profound severity. The severity of rebound insomnia is related to dose, the period of administration and the pharmacokinetics of the drug used, and in some cases the pharmacokinetics of the drug's metabolites. With a short-acting benzodiazepine (e.g. triazolam) the rapid disappearance of the drug from the receptors to which it is bound can result in severe rebound insomnia and anxiety that can last for a few days and nights after a short period of drug administration; after a more prolonged period of use, the rebound insomnia may last as long as 2–3 weeks. Drugs that are more rapidly eliminated give rise to an earlier withdrawal syndrome; withdrawal of drugs with long half-lives may have a latency of several days before rebound symptoms occur. Severe

rebound insomnia is usually more prominent in old rather than young people.

Drugs other than alcohol, caffeine and hypnotics may disrupt sleep. Common culprits include nicotine, beta-blockers, α -methyldopa, phenytoin, bronchodilators, monoamine oxidase inhibitors, amphetamine and other CNS stimulants, anorectic drugs, thiazides and other diuretics.

Patients with acute insomnia may benefit from the short-term use of hypnotics. To obtain maximum benefit, hypnotics should be prescribed at the minimum therapeutic dose and for the briefest period. Tolerance may be minimised by taking a low-dose sedative only intermittently, perhaps every third night. Despite their sedative properties, antidepressants and antihistamines should not be used primarily to treat insomnia due to their long half-lives and their peripheral side effects. The use of two sedatives simultaneously should be avoided as they may potentiate each other and result in dangerous oversedation. Most hypnotics target GABAergic activity globally in the brain. The choice of hypnotic should be informed by a match of pharmacokinetic profiles and the clinical presentation. A rapidly absorbed drug that quickly reaches a peak plasma concentration and has a rapid elimination half-life would be appropriate for a patient with acute sleep-onset insomnia but offers no benefit for an individual with early-morning awakening. Sedation during the following day is a more common effect of drugs with longer elimination half-lives. However, there is considerable variation in the elimination half-life between individuals taking the same drug. Absorption, metabolism and elimination become slower with age. Changes in protein binding, the volume of distribution of the drug as well as changes in tissue sensitivity also occur with advancing years. It is important that the plasma half-life of the drug and its active metabolites is less than 24 hours (or the interdose interval), because the drug may accumulate and cause a confusional state. Hypnotics depress respiration and so should be avoided in patients in whom respiration is already compromised, for example patients with sleep apnoea or chronic airflow obstruction. However, 'pink puffers' may benefit from the use of tranquillisers.

Circadian rhythm disturbances

Circadian disturbance of the sleep-wake rhythm may account for about 10% of insomnia. This may be due to entrainment failure that is sometimes secondary to blindness but may also occur in subjects with normal vision. Weitzman *et al.* (1981) identified a group of insomniacs with a phase-lag syndrome. Patients with the delayed sleep phase syndrome complain of sleep-onset insomnia and difficulty awakening at the desired time. Typically they experience chronic difficulty falling asleep until 2–6 a.m. but do not have difficulty maintaining sleep. There is a severe or, very rarely, absolute inability to advance the sleep phase and enforced

wake times result in sleep deprivation. Daytime sleepiness and irritability, particularly in the morning hours, depends largely on the amount of sleep loss that has resulted from the patient's effort to wake up 'on time'. Patients usually score very high as 'owls' on the 'owl-lark' scale (Horne & Ostberg 1976) and feel most alert during the late evening and night hours. When given the opportunity to sleep late, for example on holidays or weekends, waking times are fairly consistently delayed. Hypnotic drugs and alcohol may complicate the presentation and a sleep-wake log may help to demonstrate the pattern of insomnia. Patients often try hypnotics in an effort to advance sleep onset but they are rarely effective in normal doses, although they may aggravate morning sleepiness. The syndrome usually develops in adolescents, although childhood cases have been described. Familial cases have been reported and it appears to be more common in males. Motor activity monitoring and melatonin profiles are normal (Alvarez *et al.* 1992). Sleep hygiene is very important. Depression should be considered if the symptoms are refractory to behavioural intervention in an apparently cooperative patient.

An advanced sleep phase syndrome, with sleep onset at 8–9 p.m. and waking at 3–5 a.m. has been recognised but is much less common than delayed sleep phase syndrome. Recent studies have shown that mutations in the *hPER2* gene are associated with autosomal dominant familial advanced sleep phase syndrome (Taheri & Mignot 2002). Certainly early-onset sleep and waking cause much less social and work disruption than the opposite pattern.

Disturbance of circadian rhythms may be due to damage of the circadian pacemaker in the hypothalamus, perhaps as a result of a tumour. A totally irregular sleep-wake pattern is occasionally seen following head injury.

Narcolepsy

The narcoleptic syndrome is characterised by excessive daytime sleepiness with attacks of daytime somnolence, usually irresistible in intensity and leading to several short episodes of sleep per day ('narcoleptic attacks'). Cataplexy, in which the patient abruptly loses muscle tone in response to some emotionally provoking stimulus, usually laughter, must also be present in order to make a definite diagnosis. Hypnagogic hallucinations and episodes of sleep paralysis are also characteristic of the syndrome in its most complete expression, and considerable disturbance of nocturnal sleep commonly occurs.

Gelineau (1880) gave the first definite description of the disorder, and analysed 14 cases in his monograph (Gelineau 1881). Thereafter, the term 'narcolepsy' came to be applied rather indiscriminately to many varieties of morbid somnolence, some due to structural brain lesions and others associated with psychiatric disorders, resulting in a good deal of nosological confusion and faulty discussion about aetiology.

Gradually the condition was established as a distinct disease entity. Both the strong association with the human leucocyte antigen (HLA) discovered in 1984 (Honda *et al.* 1984; Langdon *et al.* 1984) and low cerebrospinal fluid (CSF) hypocretin levels are most closely associated with cataplexy rather than any of the other features of the syndrome. Association with these biological markers underscores the specificity of cataplexy in clinical diagnosis. The great majority of cases have no gross structural brain pathology but microscopic post-mortem studies have found absence of the 50 000 cells that produce preprohypocretin in the lateral hypothalamus. Family members may have narcoleptic symptoms, particularly the relatives of non-HLA-associated cases. Fresh interest has been brought to the syndrome since the finding of a mutation in the gene coding for one of the hypocretin receptors in narcoleptic dogs and the demonstration of a narcolepsy-like state in preprohypocretin knockout mice. However, with one interesting exception, narcoleptic humans do not have mutations of the genes coding for preprohypocretin or either of its known receptors (Mignot 2004).

Clinical features

Detailed accounts of the disorder are to be found in Guilleminault *et al.* (1976) and Parkes (1985). The onset is usually between the ages of 10 and 30 years and is rare after 40. The precise time of onset may be hard to determine, relatives often becoming aware of the problem before the patient himself. Males and females are probably equally liable to the disorder. At least one-quarter of cases have relatives with excessive daytime sleepiness but cataplexy is rare except in the 2% of families where the proband does not carry the HLA type DQB1*0602 usually associated with the syndrome. Of the handful of HLA-typed twins reported in the literature, only the HLA-non-associated cases were concordant for cataplexy.

Approximately three-quarters of cases have at least one of the accessory symptoms in addition to excessive daytime sleepiness and cataplexy: hypnagogic hallucinations in 20–80% and sleep paralysis in 20–60%. The 'tetrad' of all four symptoms occurs in less than 10%. Between 60% and 80% of patients complain of poor nocturnal sleep. Diagnostic uncertainty may arise in the early stages of the disease when narcoleptic attacks antedate the development of cataplexy. In a large series of patients with cataplexy, Yoss and Daly (1960) found that this had set in at the same time as the narcoleptic attacks in 55%, 1–5 years later in 25% and more than 10 years later in 15%. One may therefore encounter patients in whom daytime sleep attacks constitute the sole manifestation for some considerable time. Cataplexy antedating narcolepsy is distinctly uncommon but 'isolated cataplexy', without excessive daytime sleepiness, has been reported. In contrast, sleep paralysis and hypnagogic hallucinations are frequently

encountered in the general population. These relatively non-specific symptoms may be precipitated by drugs or changes in sleep habit.

Once it has commenced the disorder appears to persist throughout life. Apparent diminution in severity may be the consequence of deliberate effort to avoid the emotionally provocative stimuli of cataplexy, strategic napping during the day and/or the effect of medication. However, there is no evidence that long-term use of any medications alters the eventual prognosis. Very occasionally remissions and exacerbations have been described, but in most large series this has not been the case. Narcolepsy does not appear to affect lifespan.

Narcoleptic attacks consist of an overwhelming sense of drowsiness, usually leading to a brief period of actual sleep. They are commonly of daily occurrence and with several attacks per day. The period of sleep usually lasts some 10–15 minutes though may be much longer according to circumstances. If the majority of attacks exceed 30 minutes, Roth (1980) classifies the disorder as idiopathic hypersomnia. However, both long and short sleep episodes occur in the daytime in patients with narcoleptic syndrome, as well as in patients with daytime drowsiness from other causes such as sleep apnoea, and the boundary between short sleep attacks and more prolonged daytime sleep episodes is sometimes doubtful (Parkes 1985). The patient may complain either of episodic sleep attacks with reasonable alertness between, or more rarely of fighting a constant battle against drowsiness during the day. Yoss and Daly (1957) divided the syndrome into type I and type II varieties on this basis. Patients with circumscribed sleep attacks will often be found to have episodes of quite profound drowsiness between, although they may not themselves be fully aware of this. Brief 'microsleeps' lasting 10–20 seconds are also common, as shown by electroencephalography (EEG), yet may not be apparent to the patient or observers.

Sleep episodes are commoner in situations normally conducive to drowsiness: after meals, in monotonous, warm surroundings, whilst travelling and as the day progresses. Usually there is a period of a minute or two during which the patient struggles against actual sleep. However, in severe examples attacks can occur in any situation: while talking, eating, working or when engaged in other activities. Attacks while swimming or driving may very occasionally endanger life, though the prodromal drowsiness will almost always serve as a warning. Some patients are extremely irritable when prevented from falling asleep or when suddenly awakened. Typically the patient awakes refreshed, and there is then a refractory period of several hours before the next attack can occur. Some, however, remain drowsy and obtunded on awaking.

Cataplectic attacks consist of sudden immobility or decrease of muscle tone, which may be generalised or limited to

certain muscle groups. In severe attacks the patient collapses in a flaccid heap and is totally unable to move or speak. Serious falls and injuries are uncommon because there is usually a brief period of awareness preceding episodes of generalised cataplexy where the subject can assume a protective posture. Tendon reflexes are abolished for a while and extensor plantar reflexes have been observed. However, the patient typically remains fully alert and is aware of what is proceeding around him. Mild episodes may show only as drooping of the jaw, head nodding, or a sense of weakness obliging the patient to sit down or lean against a wall. Objects may be dropped or the knees buckle. Dysarthria, aphonia or ptosis may accompany attacks, and double vision or momentary difficulty with focusing may be the sole manifestation. Facial fasciculation is not uncommon and is the result of oscillating degrees of paresis. Brief partial cataplexy may be so subtle as to pass unnoticed by others. Pallor, pupillary dilation, sweating and an increase in pulse rate are sometimes observed but may be due to the shock that precipitated the attack and not the attack itself. The respiratory muscles are relatively spared and incontinence, when it occurs, is not due to cataplexy but to stress. Very occasionally, consciousness may be briefly clouded during attacks but this should be regarded as exceptional (Roth 1980).

The attacks are of short duration, usually lasting several seconds and rarely more than a minute. Occasionally, the emotional response of the patient, either to the original stimulus or to the cataplexy, may provoke further episodes of cataplexy in succession. This is called status cataplecticus. Alternatively, status cataplecticus may occur spontaneously without any apparent trigger. Status cataplecticus is confined to patients with severe cataplexy and may last minutes, hours or days. It is most likely to occur at the onset of the illness or during tricyclic drug withdrawal. The frequency and severity of cataplexy varies from several episodes per day to a single attack in many years. Episodes are more likely to occur when background vigilance is low, particularly after sleep deprivation or the use of sedative drugs (Parkes 1985).

Over 95% of cataplexy attacks are the result of sudden increases in emotional arousal. The typical triggering stimuli are so specific that cataplexy can almost always be diagnosed with confidence. Precipitation by emotional stimuli is usually strikingly evident in the history, in particular precipitation by laughter. Cataplexy is also likely to occur when the subject feels a combination of excitement, anticipation and the need for a motor response, for example during sport, sexual intercourse, being tickled, hunting, attempts at repartee, showing off or joke telling, but any strong emotion may bring on an attack: surprise, fear, outbursts of anger or feelings of exaltation. Cataplexy may very occasionally be precipitated by sneezing, coughing or nose blowing. Many patients learn to avoid provoking situations, and to check any inclination to laugh in order to avoid attacks. Sometimes, however, they can occur without any discernible affective stimulus.

Cataplexy may occur with no hint of excessive sleepiness. One possibility is that isolated cataplexy is an unusual manifestation of the narcoleptic syndrome in which the other symptoms have not yet made their appearance. In individual cases presenting with cataplexy it is not possible to predict whether they will develop additional symptoms of the narcoleptic syndrome (Roth 1980). Bogaert (1936) first described its familial occurrence. Geladi and Brown (1967) reported a rare example of a family in which typical laughter-induced cataplexy appeared to be transmitted as an autosomal dominant trait. Eleven members were affected from childhood onwards, with no hint of narcoleptic attacks in eight. Sleep paralysis was an occasional accompaniment. Roth (1980) reported families with cataplexy only and no other symptoms of the narcoleptic syndrome. HLA typing has not been reported in these families.

Hypnagogic hallucinations are vivid perceptual experiences occurring at sleep onset, often with the realistic awareness of the presence of someone or something. Up to 50% of narcoleptic individuals have frequent hypnagogic hallucinations but some are anxious about disclosing their experiences because they erroneously fear a psychiatric aetiology. Hypnagogic episodes in normal subjects occur in stage 1 NREM sleep, whilst those of narcoleptics are often accompanied by REM sleep and so should more accurately be termed 'pre-sleep dreams' (Parkes 1986). In the narcoleptic syndrome, pre-sleep dreams most commonly occur in multiple modalities, usually auditory, visual and/or tactile. They are experienced during the transition from wakefulness to sleep, or rather less commonly during the phase of recovery from sleep (hypnopompic dreams). Not uncommonly they occur simultaneously with episodes of sleep paralysis. They may be experienced in the middle of the night when the patient has roused for a while, and they sometimes accompany daytime narcoleptic attacks. Typically, pre-sleep dreams are intensely vivid and seem to be real at the time. The patient may react momentarily in accordance with what he is experiencing. Later, however, when fully awake, he almost always recognises their alien character. Lively accompanying affects, especially of terror, are widely reported as characteristic. Roth and Bruhova (1969) stressed the kaleidoscopic nature and bizarre character of the visions. (Zarcone 1973) suggested that the pre-sleep experiences of narcoleptics differ from those of normals in their complex dream-like quality and the intensity of the accompanying emotion, whereas non-narcoleptics usually experience a mere word or image with little affective meaning.

Sleep paralysis consists of attacks of transient inability to move that emerge in the stage between wakefulness and sleep. In narcoleptics they typically occur while falling asleep, both at night and with daytime sleep attacks. Usually they are infrequent, rarely occurring more than once or twice per week.

The onset is abrupt, with the patient suddenly aware that he can neither speak nor move. The paralysis is flaccid and usually complete, though some patients can open their eyes or even cry out briefly. As with cataplectic attacks the episodes are brief, lasting several seconds and rarely more than a minute. Unlike cataplexy, the episode is usually dispelled abruptly if the patient's name is called or if he is touched or shaken. Otherwise it resolves spontaneously. Intense alarm is usually provoked. Dream mentation sometimes accompanies the attack and may lead the patient to fear that he is to be harmed or attacked.

Sleep paralysis is not specific to the narcoleptic syndrome and may occur in up to 62% of the normal population (Dahlitz & Parkes 1993). It is more likely at times of sleep disruption, for example with jet-lag or the use of sedative hypnotic medication. Frequent sleep paralysis without other symptoms is very rare but may be strongly familial (Roth & Bruhova 1969).

Disturbed nocturnal sleep is also characteristic of narcoleptics, occurring in 60–80% of patients. They fall asleep promptly but thereafter are restless, wake again often and may speak, shout or even walk about the room. Sleep myoclonus occurs in up to half of patients. The lost nocturnal sleep is made up during the daytime, so overall the total sleep time per 24 hours is normal. Vivid and terrifying dreams are common, occurring in some 60% of patients with the narcoleptic syndrome and some 20% of those with excessive daytime sleepiness alone (Roth & Bruhova 1969). Themes of murder or of being pursued are said to be common.

Other symptoms. A variety of other symptoms are reported from time to time. Somnambulism is occasionally a pronounced feature. A rapid weight gain at onset may be observed, and libido or potency may become impaired. Hypogonadism, a feminine hair distribution, polyuria and polydipsia are very occasionally present. Bouts of amnesia can occur as an occasional complication; the patient suddenly realises he has no knowledge of the past few minutes and has to check what has been done, usually discovering that he has continued to function normally during most of the time. Roth (1980) and Parkes (1986) also report that automatic behaviour may feature in narcolepsy. The patient tries to overcome his sleepiness and carry on activities but loses awareness of what transpires; he may continue talking without making sense, his handwriting may suddenly change to meaningless scribble, or he may continue walking and wake in fresh surroundings. Such episodes are prone to occur in one-third of patients, sometimes closely resembling episodes of transient global amnesia.

Differential diagnosis

Sometimes the patient's symptoms have long been attributed by relatives or employers to laziness, irresponsibility or emotional instability. There are no abnormalities on physical

examination or routine laboratory tests, and the diagnosis rests essentially on a careful history. REM episodes at sleep onset may be discovered with polysomnography, and although they may support a diagnostic suspicion the clinical history has proved the most robust basis for diagnosis in genetic studies. HLA typing may be useful in confirming the diagnosis, since if the patient is negative for the HLA antigen in question (DQB1*0602) the diagnosis of narcolepsy must be considered very unlikely (Parkes 1986).

In mild cases of excessive daytime sleepiness it may be impossible to draw a definite distinction from normal drowsiness. In the absence of the classic accessory symptoms it can be important to note that attacks of drowsiness are irresistible despite the absence of fatigue, or that attacks occur in inappropriate circumstances. The Epworth Sleepiness Scale (Box 13.1) (Johns 1991) is a clinically useful self-rating scale of excessive daytime sleepiness. Epworth Sleepiness Scale scores correlate well with far more expensive and time-consuming sleep laboratory investigations.

Box 13.1 The Epworth Sleepiness Scale. (Reprinted with permission from M. Johns.)

Name: _____

Today's date: _____ **Your age (year):** _____

Your sex (male = M; female = F): _____

How likely are you to doze off or fall asleep in the following situation, in contrast to feeling just tired? This refers to your usual way of life in recent times. Even if you have not done some of these things recently try to work out how they would have affected you. Use the following scale to choose the most *appropriate number* for each situation:

- 0 = would *never* doze
- 1 = *slight* chance of dozing
- 2 = *moderate* chance of dozing
- 3 = *high* chance of dozing

Situation	Chance of dozing
Sitting and reading	_____
Watching TV	_____
Sitting, inactive in a public place (e.g. a theatre or a meeting)	_____
As a passenger in a car for an hour without a break	_____
Lying down to rest in the afternoon when circumstances permit	_____
Sitting and talking to someone	_____
Sitting quietly after a lunch without alcohol	_____
In a car, while stopped for a few minutes in traffic	_____

Thank you for your cooperation

Fatigue based on anxiety or depression is a common misdiagnosis, especially if the patient presents his complaint as a feeling of tiredness instead of describing periods of excessive sleepiness. Neurosis is liable to be suspected when emotional complications have arisen from disrupted social or economic circumstances. However, narcoleptics rarely complain of muscular and physical exhaustion as do patients with fatigue of emotional origin, and they often awake from naps refreshed whereas the neurotic patient does not. The depressed and anxious patient will rarely complain of drowsiness as such, nor of recurring periods of uncontrollable sleep.

Hysterical dissociation may occasionally take the form of sleep, but this typically follows well-defined precipitants. The hysterical 'sleep' represents an active withdrawal, is usually prolonged, and the patient resists being woken. The question of hysteria or of schizophrenia may be raised when hypnagogic phenomena are particularly vivid or fantastic. Daniels (1934) described such a patient who saw forms appearing at the windows and entering the room, and felt as if snakes, birds and other creatures were moving about in her abdomen and emerging from her mouth. All such symptoms disappeared with ephedrine.

Hypothyroidism may be the initial diagnosis when the patient complains of dullness and fatigue, or hypoglycaemia when he describes dizziness or light-headedness as part of the attacks. Epilepsy will be suspected when the episodes are described as 'black-outs', but a careful history will reveal drowsiness before the loss of consciousness and full alertness on recovery. Witnesses will describe an episode of normal sleep from which the patient can be woken and the absence of convulsions. Cataplectic attacks may be mistaken for petit mal akinetic seizures. Precipitation by emotion and the preservation of full alertness are important distinguishing features.

Some patients first seek help on account of diplopia due to latent ocular imbalance brought about by episodes of drowsiness: multiple sclerosis or myasthenia gravis may then be suspected. Attacks of diplopia or ptosis may also be the principal manifestations of the patient's cataplexy. In older patients cataplexy may be mistaken for drop attacks due to vertebrobasilar insufficiency. Early symptoms of dementia may occasionally be attributed to narcolepsy.

The history will usually distinguish narcolepsy from other hypersomnias, such as idiopathic hypersomnia, Kleine-Levin syndrome or sleep apnoea syndrome. The presence of obesity may cause confusion with the latter. Hypersomnia due to structural brain lesions is likely to be long-lasting and with other ancillary evidence by way of neurological abnormalities.

Aetiology

The precise cause of narcolepsy remains elusive. The extremely close association between narcolepsy and HLA

class II antigens in linkage disequilibrium with DQB1*0602 raises the possibility of an immunological basis, especially since these antigens are widely distributed in the brain, but this remains to be clarified. Administration of IgG and corticosteroids to a case of developing narcolepsy was not sufficient to abort disease development and no discernible benefit was derived from the administration of IgG in two established cases.

In Labrador and Doberman dogs, narcolepsy is caused by a mutation in the *hcrt*-2 receptor gene. There is evidence that absence of *hcrt*-2 receptors eliminates hypocretin-evoked excitation of histaminergic neurones in the hypothalamus, which gate NREM sleep onset in mice (Willie *et al.* 2003). Preprohypocretin gene knockout mice and a mouse model with ataxin-3 driven hypocretin cell loss have abnormal wake-REM transitions, behavioural arrests possibly analogous to cataplexy and increased sleep during the active period (Mignot *et al.* 2002a). These findings have led to the conclusion that narcolepsy is caused by deficient hypocretin neurotransmission in these animals. Administration of hypocretin can reverse symptoms of narcolepsy in animals (Siegel 2004).

In humans, CSF hypocretin levels are abnormally low in many subjects with the narcoleptic syndrome, although low CSF hypocretin-1 levels may also be low in some subjects with excessive daytime sleepiness and hypersomnia (Krahn *et al.* 2002; Mignot *et al.* 2002b; Ebrahim *et al.* 2003; Martinez-Rodriguez *et al.* 2003). At post-mortem the number of preprohypocretin cells in the lateral hypothalamus of narcoleptic subjects has been found to be significantly lower than in controls. Some authors have suggested that the absence of preprohypocretin cells with increased gliosis in the region but preservation of the intermingled cells is evidence of specific, possibly immune mediated, destruction of the preprohypocretin cells. A single case has been reported of a mutation in the human preprohypocretin gene which resulted in unusually severe symptoms that developed in early childhood. However, unlike dogs most human narcoleptics do not have mutations in any of the hypocretin genes. This also applies to the rare HLA-DQB1*0602-negative subjects, who appear to have more affected relatives than HLA-DQB1*0602-positive subjects. Although the cause is still unknown in humans, depletion of hypocretin in both animals and humans is associated with the development of narcoleptic symptoms. However, many narcoleptic subjects who are clinically indistinguishable from those with low CSF hypocretin have normal hypocretin levels. The role of the hypocretins in relation to the critical balance between catecholamines, serotonin and acetylcholine in the pons is unknown and the disease pathway in narcolepsy has yet to be explained.

In very occasional patients narcolepsy has been reported in the presence of structural brain pathology (secondary narcolepsy) but the authenticity of most of these cases is doubtful (Parkes 1985). Indeed the rarity of clear-cut examples

would suggest that coincidence has often been responsible. Thus narcolepsy has been described with tumours of the hypothalamus and third ventricle, also with general paresis, cerebral arteriosclerosis and multiple sclerosis. Occasionally it has followed encephalitis or head injury, sometimes after a considerable interval.

Most cases with cerebral pathology are atypical, and are probably more accurately regarded as hypersomnias than narcolepsy, having sleep of long duration or sustained severe drowsiness. Cataplexy has been extremely rare in such examples. The exception appears to be encephalitis lethargica, which has occasionally been followed by cataplexy as well as narcolepsy (Adie 1926; Sours 1963), but again these cases have usually been atypical in that they tend to recover and show pupillary abnormalities and personality changes. When narcolepsy and cataplexy are found together, it is unusual to find any evidence of structural brain disease.

It has been established that routine EEG shows no abnormalities in narcolepsy, beyond the expected changes when the subject is drowsy and the normal sleep changes while asleep. During cataplectic attacks and episodes of sleep paralysis, the EEG remains unchanged. However, more discriminating assessment of the stages of sleep shows interesting differences from normals. Rechtschaffen *et al.* (1963) discovered a distinctive feature in the nocturnal sleep of narcoleptics, namely that a REM period occurred at the onset, or shortly after the onset, instead of after the usual period of 90 minutes or so. Daytime sleep attacks have also been shown to consist of REM-type sleep, most often when the patient suffers from cataplexy as well as excessive daytime sleepiness (Dement *et al.* 1964, 1966; Hishikawa & Kaneko 1965; Hishikawa *et al.* 1968). In patients with excessive daytime sleepiness alone, however, the early REM phase may not be seen, and daytime attacks may be accompanied by NREM slow-wave sleep. Pre-sleep dreams and sleep paralysis have proved to occur exclusively in the sleep-onset REM periods, and where recordings could be obtained during cataplectic attacks the REM picture was again obtained. Night-time sleep is also generally deranged. In addition to direct or early onset into REM there are often marked phasic REM bursts, poorly regulated sleep cycles, many shifts of phase and frequent awakenings. Altogether, sleep-onset REM may help to confirm a diagnosis of narcolepsy, emerging in over 95% of cases if daytime naps are studied as well as sleep recordings (Parkes 1985). However, false diagnoses may occur if patients have not adhered to the strict recording requirements, particularly relating to the use of sedative and stimulant drugs and sleep episodes during the period immediately prior to the study. Moreover, the cost of sleep studies may restrict their widespread use.

Thus it seems that the pathogenesis of the narcolepsy syndrome lies in an abnormality of REM sleep timing and the dissociation of different aspects of REM (the dream mentation and the motor inhibition) which then appear when the

patient is conscious. It is likely that the NREM system is abnormal as well, as witnessed by the frequent periods of drowsiness that occur apart from attacks of sleep, also the frequent failure of nocturnal NREM sleep to reach the normal depth (Roth & Bruhova 1969).

Genetic factors have emerged as significant in the narcoleptic syndrome. Many authors have found a family history of excessive daytime sleepiness in approximately one-third of narcoleptic probands. It is very rare for multiple cases of cataplexy to occur in a family unless they do not carry the HLA-DQB1*0602 haplotype associated with the disease. Although there are very few case reports, affected subjects in HLA-DQB1*0602-negative families sometimes do not carry the same HLA type. In these cases the disease may be caused by genes remote from the HLA system, but no mutations have yet been found in the preprohypocretin gene or either of the hypocretin receptor genes in HLA-DQB1*0602 familial cases. Environmental factors may contribute to familial clustering. However, HLA-DQB1*0602-negative half-sisters who were reared apart from birth both developed the narcoleptic syndrome in adulthood, suggesting that if common environmental factors were important here, the effect occurs very early in life. One study shows that more narcoleptic individuals are born in March and fewest in September. This suggests that environmental factors during the fetal or perinatal period may be important (Dauvilliers *et al.* 2003). Twin studies of the narcoleptic syndrome are too few to allow an estimate of the relative concordance between monozygotic and dizygotic pairs. Of more than a dozen reported monozygotic twin pairs, only two have been reported to be concordant. This may appear to implicate environmental factors, but could be an artefact of reporting bias.

Treatment

The treatment of narcolepsy is outlined by Parkes (1985) and Cooper (1994). Analeptic drugs are the mainstay of treatment for daytime sleep attacks, though their use is unsatisfactory in a number of ways. High dosage of amphetamines may be required to control attacks, resulting in side effects of insomnia, anorexia, irritability, tremor, hypertension and, on rare occasions, acute paranoid psychoses. Moreover, when pushed to high dosage nocturnal insomnia may lead to an increase in daytime drowsiness and sleep attacks. Addiction is an additional risk, though this appears to be rare among narcoleptics.

In practice it is best to try the effect of one of the less potent stimulant drugs, such as mazindol or modafanil, and reserve dexamfetamine sulphate (Dexedrine) or methylphenidate (Ritalin) for those whose symptoms are not adequately controlled. Alternative preparations can be tried when difficulties arise. High doses may produce unwanted effects, such as sweating and irritability, and may have the paradoxical effect of increasing rather than reducing daytime drowsiness. In

many patients tolerance can be controlled by using low doses of short-acting stimulants only as required. Stimulants suppress the REM stage of sleep, and this may contribute to the therapeutic effect in narcolepsy. However, these drugs do not improve cataplexy and usually have little effect on the other symptoms.

Cataplexy is helped by tricyclic antidepressants such as imipramine and desipramine and particularly by clomipramine (Anafranil). The latter has been shown to be effective in a dosage considerably lower than is required for an antidepressant effect, the cataplexy often lessening within 24 hours of starting treatment. Sleep paralysis and hypnagogic hallucinations are also reduced. Tricyclic antidepressants have no direct effect on narcoleptic sleep attacks, but when employed with amphetamines they may allow the dosage of these to be reduced. In theory the combination could be dangerous, with risk of hypertensive crises, but Zarcone (1973) employed imipramine with methylphenidate in 45 cases with no apparent harm. Selective serotonin reuptake inhibitors and the serotonin and noradrenaline (norepinephrine) reuptake inhibitor venlafaxine may control cataplexy with fewer side effects than the tricyclics. Most narcoleptics avoid alcohol because of its sedative effects and consume caffeine only in the mornings to avoid sleepless nights.

Counselling has an important part to play, with advice about acquiring a regular pattern of sleep and daytime activities, and perhaps establishing schedules for daytime naps to ward off spontaneous attacks. Shiftwork must be avoided, or work where drowsiness or falls could be a hazard. In general, untreated subjects should not drive and patients must inform their car insurance company of their diagnosis to ensure that they will be covered in case of a driving accident. Psychotherapy may help where social and personal adjustments must be made to the disability.

The impact of the disorder on patients' lives was illustrated in a questionnaire study by Broughton and Ghanem (1976). Many reported recurrent depression, often severe, and almost half described subjective worsening of memory since the onset of the disease. Employment difficulties were common, both on account of sleep attacks and personality difficulties. A surprising number had suffered accidents, either while driving or while engaged in household activities. Recreational pursuits were commonly hampered to a distressing degree.

Roth (1980) reviewed evidence of a special association between narcolepsy and depression, which appeared to be commoner than in the general population. The sleep attacks tended to become more pronounced during phases when the patient was depressed.

Other sleep disorders

Other syndromes of sleep disturbance have come to be recognised, including idiopathic hypersomnia, hypersomnia

with 'sleep drunkenness', the sleep apnoea syndromes and Kleine-Levin syndrome. In addition there are hypersomnias based on identifiable cerebral disease and metabolic dysfunction, and others which appear to be based on psychological factors alone. Brief mention will also be made of the parasomnias, including somnambulism and 'night terrors', which very occasionally come to medical attention in adult patients. REM sleep behaviour disorder arises in older adults and must be distinguished from epilepsy.

Surveys show enormous variation in referral rates of these various conditions to specialist sleep clinics depending on the local availability and subspecialisation of sleep services. Coleman *et al.* (1982) surveyed almost 4000 patients attending sleep disorder clinics in the USA. Half suffered from some form of hypersomnia, one-third from insomnia and 15% from a parasomnia. Of the hypersomnias, 43% represented sleep apnoea syndromes, 25% narcolepsy, 9% idiopathic hypersomnia, and 5% other hypersomnias including sleep drunkenness and Kleine-Levin syndrome; 4% appeared to be due to psychiatric disorder, mainly depression, 3% to medical or toxic conditions and 2% to drugs or alcohol.

Idiopathic hypersomnia

Under this title Roth (1980) delineated a sizeable group of patients rarely mentioned in the literature but considered by him to represent an independent nosological entity. Among patients referred to Roth's clinic in Prague, this group came second only to narcolepsy in frequency. Others, however, have found it less frequently, and in particular much less commonly than the sleep apnoea syndrome as shown in Coleman *et al.*'s survey above.

The chief difference from narcolepsy lies in the longer duration of the daytime sleeps, which typically last from half an hour to several hours at a time. Cataplexy and the other classic accessory symptoms of narcolepsy are absent. The periods of daytime somnolence lack the irresistible quality of narcolepsy but the patient is nevertheless obliged to fight against sleepiness for a large part of the day. The daytime naps are not refreshing and are typically preceded by long periods of drowsiness (Guilleminault & Faull 1982). 'Microsleep' episodes may be detected by continuous recordings, especially when trying to read or watch television, but also at times during conversation. At night the patient falls asleep quickly and sleeps deeply, often with difficulty waking in the morning. Sleep drunkenness (see below) may be a feature on rising. Prolongation of nocturnal sleep may be present, as well as daytime somnolence. At weekends some patients sleep more or less continuously while undisturbed. Sleep-onset REM is not detected, and daytime sleep is of the NREM type (Cooper 1994).

Idiopathic hypersomnia is suspected clinically when daytime somnolence is the sole symptom, i.e. in the absence of the accessory symptoms of narcolepsy, of snoring at night

or of nocturnal sleep disturbance. Polysomnography confirms the lack of nocturnal apnoeic periods or hypoventilation. A significantly increased amount of stage 2 NREM sleep may be detected along with a decrease in stages 3 and 4 (Guilleminault & Faull 1982).

The condition sets in usually between the ages of 10 and 20, developing over the course of several months and then tending to remain stable as a source of lifelong disability. Occasionally the onset may be later, even well into middle age. Males are affected slightly more commonly than females. In some 30% of cases it occurs familiarly. In all these respects the resemblance to narcolepsy is obvious.

Among Roth's 167 cases, almost half showed psychological difficulties (neurotic problems, personality disturbances and depression). During phases of depression the periods of sleepiness were usually increased. Sexual problems occurred in 16%, with lack of libido or potency in the men and menstrual disturbances in the women. As with narcolepsy, problems with education, jobs and recreation were frequent, and often even more severe on account of the long duration of daytime sleeps.

The cause is unknown but presumably rests on biochemical disturbances of the neural mechanisms underlying sleeping and waking. Roth discounted psychogenic factors, likewise any known brain pathology, by his criteria for accumulating the sample. EEG and polygraphic records showed NREM patterns to be prominent during diurnal sleeps, often proceeding to stages 3 and 4. All-night records revealed normal sleep organisation except for its long duration. Treatment consists of the administration of central stimulant drugs, as in narcolepsy, but response is often poor.

Hypersomnia with sleep drunkenness

Roth *et al.* (1972) initially reported this as an independent clinical syndrome, representing 30% of the patients in Prague who were referred for investigation of sleep disturbances. Now, however, it is viewed essentially as a variant or complication of idiopathic hypersomnia (Roth 1980).

Sleep drunkenness consists of difficulty in achieving complete wakefulness, accompanied by confusion, disorientation, poor motor coordination, slowness and repeated returns to sleep. A large group of patients showed this as a chronic symptom, occurring with almost every awakening and typically persisting as a lifelong tendency (Roth *et al.* 1972). In the great majority daytime hypersomnia was present as well. The patients were rarely capable of waking spontaneously but needed vigorous and persistent stimulation. Even when so awakened they were confused, disorientated and ataxic in a manner resembling drunkenness for between 15 minutes and 1 hour or longer. Many showed impaired efficiency for up to 4 hours.

The majority reported extremely deep and prolonged nocturnal sleep, often failing to wake spontaneously for 16–17 hours. At night they fell asleep rapidly within seconds of

retiring. Associated symptoms consisted of headache, recurrent depression, difficulty with concentration or emotional lability. Eight patients had severe personality disorders or showed psychotic features. However, there was no characteristic personality type or psychopathology, and psychiatric symptoms were not invariable accompaniments.

The course appeared to be stationary in the absence of treatment: once declared, the disability could last until advanced age. Most patients responded well to analeptic drugs taken by day and immediately before retiring. Alternatively, they could be administered immediately after the initial awakening, the patient being allowed thereafter to sleep for half an hour more, after which he would either wake spontaneously or could be easily roused.

In 52 of the 58 examples there was no apparent cause. Six were possibly symptomatic of brain disorder, setting in shortly after severe head injury, encephalitis or a cerebrovascular accident. In the idiopathic cases the pathophysiology remained obscure. Essentially, the disorder appeared to represent an extension and intensification of the normal processes of sleep.

Apart from the chronic syndrome described above, sleep drunkenness can also occur as an occasional symptom in healthy persons if, for example, they are suddenly awakened after too little sleep. It is facilitated by fatigue or the consumption of alcohol or hypnotics before retiring. It has also been described in persons of irritable disposition and in people subject to frequent terrifying dreams. Roth *et al.* (1972) refer to such examples in the older psychiatric and criminological literature, including persons who have become aggressive or even homicidal while in a state of sleep drunkenness.

Sleep apnoea syndromes

The importance of hypersomnias accompanied by alveolar hypoventilation has been increasingly recognised. Best known is the Pickwickian syndrome, so-called by Burwell *et al.* (1956) after the fat boy of *Pickwick Papers*. However, this is merely a special instance of a general class of problems. The topic is comprehensively reviewed by Parkes (1985), Whyte *et al.* (1989) and Douglas (1994).

A division is traditionally made into apnoeas of obstructive or central origin, but this is now regarded as being to some extent artificial. The great majority, over 90%, are associated with airway obstruction and it is this that must be detected if treatment is to be successful. The rarer 'central' forms include those associated with lesions of the medulla due to a variety of congenital or acquired pathologies, and 'Ondine's curse', seen mainly in infants, in which abnormalities of the respiratory centres are manifest as loss of automaticity of breathing while asleep (Severinghaus & Mitchell 1962). Rare familial forms are probably due to inherited insensitivity of the respiratory centres to hypercapnia. An element of obstructive apnoea usually accompanies these central cases because the pharyngeal and

diaphragmatic muscles are responsive to chemical respiratory stimuli.

Obstructive sleep apnoea is usually due to occlusion or narrowing of the upper airway behind the tongue or palate. Fibreoptic endoscopy shows that the lateral walls of the oropharynx oppose during episodes of apnoea, commencing with constriction in the upper oropharynx (Parkes 1985). During inspiration the pressure within the upper airway is always subatmospheric, and the patency of the airway depends on the bracing effect of the surrounding musculature. Since muscle tone drops during sleep, there is an enhanced tendency towards narrowing at this time, being greatest when lung volume is minimal at the onset of respiration (Bradley *et al.* 1986). Snoring can result from the turbulent flows engendered, or periods of apnoea when occlusion is complete. Once apnoea has occurred, normal breathing is only restored following arousal for a few seconds, resulting chiefly from the negative intrapleural pressure as the patient struggles to breathe (Douglas 1994). The cycle of recurrent apnoeas and arousals may occur up to 100 times per hour, leading to great disruption of normal sleep patterns.

Many of the sufferers from sleep apnoea are obese but this is not invariable. Fat deposition in the submucous tissues around the nasopharynx then contributes to the obstruction. Others may have grossly enlarged tonsils or small mandibular size, the latter often being associated with palatal, tongue or pharyngeal deformity. Rarer causes are hypothyroidism, acromegaly, failure of the laryngeal abductors (as in Shy-Drager syndrome) or myotonic dystrophy, which leads to respiratory muscle stiffness and weakness.

Most cases of obstructive sleep apnoea commence over the age of 40, with a steady increase in prevalence thereafter. Males outnumber females by 10:1. In contrast, the rare central forms can affect all age groups and without definite sex distribution.

The usual presentation is with excessive daytime sleepiness occasioned by the disrupted nocturnal sleep. A hallmark of the condition is loud snoring or honking at night as reported by sleeping partners, but the absence of snoring does not exclude the condition. Obesity is common, being found in perhaps 50% of subjects, often with a characteristic facial appearance caused by a short thick neck and heavy jowls. The phases of daytime sleepiness are usually profound and often compelling, leading to a significant increase in accidents including road traffic accidents (George *et al.* 1987). Among 80 patients, Whyte *et al.* (1989) reported that five had fallen asleep while driving cars, four while driving heavy goods vehicles and one while flying his private plane. The daytime naps are typically of brief duration and are frequent throughout the day. Hypnagogic hallucinations and periods of automatic behaviour may occur.

During sleep, by day and by night, respiratory disturbances give a characteristic stamp to the picture. The breathing becomes periodic, with apnoeic intervals lasting 10–20

seconds during which the level of sleep steadily deepens. Resumption of breathing is accompanied by deep sighing and guttural snoring. While the subject is apnoeic, blood oxygen falls and blood carbon dioxide rises. Muscular twitching may be marked. Nocturnal sleep is characterised by restlessness, frequent changes of posture, flailing arm movements and repeated awakenings. Nocturia or enuresis may occur. While awake, respiratory function studies typically show normal results or there may be persistent alveolar hypoventilation.

Reported complications include pulmonary hypertension resulting from the increase in pulmonary blood pressure during apnoeic periods, and cor pulmonale with right heart failure. Systemic hypertension may develop, likewise cyanosis and polycythaemia. The classic Pickwickian syndrome consists of somnolence with obesity, cor pulmonale and secondary polycythaemia, coupled with daytime hypoxia and carbon dioxide retention. Cardiac dysrhythmias, myocardial infarction and cerebrovascular accidents may contribute further to mortality in marked examples of the syndrome. Not surprisingly, a high incidence of unexpected deaths has been reported (MacGregor *et al.* 1970).

These varied adverse effects on health have been widely discussed in the literature, but it can be difficult to apportion the blame between sleep apnoea *per se* and the confounding effects of such variables as obesity and age. In a systematic review of the evidence, Wright *et al.* (1997) conclude that a causal association between sleep apnoea and a range of poor health outcomes has not been firmly established, except with regard to daytime sleepiness and possibly vehicle accidents.

In severe examples mental features can figure prominently. Many patients find morning arousal difficult, with sleep drunkenness, disorientation, headache and motor incoordination (Parkes 1985). Such difficulties may persist during the day with poor memory and concentration. Sackner *et al.* (1975) found a high prevalence of personality disturbance with paranoia, hostility and sometimes agitated depression. Millman *et al.* (1989) reported that almost half of their patients scored highly on the Zung Depression Scale, with sustained improvement once the sleep apnoea had been relieved. Sudden outbursts of violent behaviour and marked anxiety have also been attributed to the condition, likewise sexual problems including impotence.

Greenberg *et al.* (1987) have documented impairments in neuropsychological functioning in patients with sleep apnoea, more pervasive and severe than in controls suffering from other causes of daytime somnolence. Tests of attention and motor efficiency were particularly affected. The severity and duration of hypoxaemic episodes correlated significantly with measures of perceptual organisation (Block Design Test) and manual motor speed. Children with sleep apnoea may show a deterioration in school performance and failure to thrive. Guilleminault and Anders (1976) reported

that one-third of children showed borderline mental retardation when first seen. Such features, and the daytime drowsiness, appear to exceed what might be expected from insomnia and hypoxia alone, and probably owe much to the frequent shifts of sleep phase that occur throughout the night and the loss of deep slow-wave NREM sleep.

In the investigation of suspected examples it can be invaluable to obtain a history from the patient's sleeping partner. The patient himself is often unaware of his snoring and frequent brief arousals. Short of this, direct observation of the patient while asleep can be informative. Useful screening tests include lateral computed tomography of the neck to gauge any generalised airway narrowing, a 24-hour ECG to detect the bradycardia accompanying apnoeas and the rebound tachycardias that follow, or oximetry to monitor the repeated cycles of desaturation. Rauscher *et al.* (1993) have reported the value of pulse oximetry, coupled with indices of weight, height, sex, witnessed episodes of apnoea and reports of falling asleep when reading, in leading to a correct diagnosis of snorers referred to a sleep laboratory.

However, polysomnography provides the definitive diagnosis when facilities are available and permits assessment of the severity of the condition. Overnight recordings allow continuous monitoring of the EEG, the respiratory movements and airflow during sleep. Apnoeas should occur during both REM and NREM phases to be certain of the diagnosis, but are usually of greater frequency during REM sleep. Hence they are typically more severe during the second half of the night. In practice, sleep is sometimes so disrupted that little REM sleep is achieved, and little or no stage 3 or 4 NREM sleep. Concurrent oximetry allows the severity as well as the frequency of desaturations to be measured.

Treatment should first involve loss of weight when this is indicated, and the strict avoidance of alcohol in the evenings or the use of sedatives or hypnotics. Otolaryngological investigation will often be indicated to explore possibilities of remediable airway obstruction. Contributory factors such as hypothyroidism, acromegaly or retrognathia should receive attention. No truly effective drug treatment has been achieved.

Patients who fail to respond to simpler measures may, if the condition is severe, be considered for continuous positive airway pressure (CPAP) treatment each night. A pressure of 4–10 cmH₂O is applied continuously through a mask fitted over the nose and mouth to prevent the recurrent collapse of the upper airways during sleep. Many patients find that they can adjust to this satisfactorily, with consequent improvement in daytime somnolence and both physical and mental symptoms. Surgical procedures to the upper airway have sometimes been performed but their place in treatment is controversial. Nevertheless, tracheostomy still finds a place in severely compromised patients when CPAP is unsuccessful, or as an emergency when some other operative procedure must be undertaken. Occasional patients

with true central apnoeas may require intermittent positive pressure respiration while asleep.

Kleine–Levin syndrome of recurrent hypersomnia

Levin (1936) drew attention to a rare syndrome of periodic somnolence, often lasting for days or weeks at a time and associated with intense hunger. Irritability, excitement and motor unrest also characterised the somnolent phases. Kleine (1925) had earlier reported several examples. Critchley (1962) carried out a detailed analysis of the 15 cases in the literature at that time and added 11 of his own. Kleine–Levin syndrome is a long-cycle hypersomnia, the episodes being separated by months or even years of normal health.

The majority of reported cases have been in young men (68%) and with onset in early adolescence. In a review by Annulf *et al.* (2005) 186 patients were identified from 139 articles, of which there were 168 primary cases of Kleine–Levin syndrome. In this series the median age of onset was 13 years (range 4–82 years), 81% during the second decade. The median duration of the syndrome was 8 years with seven episodes of 10 days recurring every 3.5 months. The disease lasted longer in women and in patients with less frequent episodes during the first year. They found that it was precipitated most frequently by infections (38.2%). Other factors including head injury, alcohol consumption, exposure to sunlight, sea sickness or a period of physical stress have anteceded the first attack (Billiard 1981; Will *et al.* 1988).

Common symptoms were hypersomnia (100%), cognitive changes (96%, including a specific feeling of derealization), eating disturbances (80%), hypersexuality (43%), compulsions (29%) and depressed mood (48%) (Annulf *et al.* 2005).

The somnolence may set in abruptly or follow gradually after several days of mounting malaise and tiredness. The patient sleeps excessively by day and night, rousing only to eat or empty bladder and bowels. Incontinence does not occur. External stimuli will wake the patient as from natural sleep, but rousing usually results in intense irritability and truculence. The most common eating disturbance is a dramatic increase in the consumption of food. Critchley (1962) preferred the term 'megaphagia' to 'morbid hunger': compulsive eating in a wolfish and greedy manner is a conspicuous feature. The patient does not complain of hunger itself and rarely demands food when this is not in sight, although any food in the immediate vicinity will be devoured. Hypersexuality may be observed in one-quarter of subjects both during and after attacks (Parkes 1986). Occasionally, sexual behaviour may be disinhibited.

Throughout the attack there are few if any abnormal physical signs. Unexplained mild fever is sometimes reported, also pupillary changes, nystagmus or an extensor plantar response. Laboratory investigations are usually entirely normal, including examination of the CSF, though reduced growth hormone secretion has been reported (Chesson *et al.* 1991). CSF white cell counts and protein levels were normal

on all patients, ruling out infectious meningitis (Annulf *et al.* 2005). CSF levels of hypocretin-1 were normal in five patients but slightly decreased in two patients during an episode (Katz & Ropper 2002; Migrot *et al.* 2002; Dauvilliers *et al.* 2003). The EEG shows the usual changes of drowsiness or sleep, but sleep studies may show an increase in total sleep time to 12–14 hours, reduced sleep latency and REM latency, and a reduction in stages 3 and 4 of NREM sleep (Pike & Stores 1994). Elian and Bornstein (1969) reported a patient who showed paroxysmal delta and diffuse theta activity during attacks, but this is distinctly unusual. Each episode ends spontaneously, typically in a gradual manner but sometimes abruptly.

Mental abnormalities during attacks have attracted much attention.

Irritability is typically marked, extending at times to severe aggression when the patient is disturbed. Uninhibited insolent behaviour may emerge, or fidgety behaviour, agitation and tearing at the bed clothes. The bizarreness of behaviour can be an alerting sign; the patient described by Pike and Stores (1994), for example, chased a friend with a carving knife, stole a cucumber, hit a woman in the street with a bag, and repeatedly changed the position of ornaments in the home. Confusion of thought is usually evident too, with disorientation, forgetfulness, depersonalisation and muddled speech. Vivid imagery may be prominent, with waking fantasies that are difficult to disentangle from vivid dreams. Visual and auditory hallucinations may occur. One of Critchley's patients felt responsible for all the events of which he was aware, and believed he could stop a clock with his thoughts and control his own hearing and vision.

Usually the mental abnormalities subside as the period of somnolence ends, but sometimes they persist for days, weeks or a few months thereafter. Half of patients experience depressed mood during episodes. In two of Gallinek's (1954) patients, severe depression persisted for several weeks after every attack, with suicidal tendencies, retardation and pathological guilt. A period of elation lasting several weeks has occasionally been reported (Gilbert 1964), also a phase of sexual hyperactivity when the sleep is over (Passouant *et al.* 1967). Quite often anorexia, headache and malaise follow the attack before the patient feels fully refreshed and regains normal clarity of thought. Thereafter, however, the normal personality is resumed, usually with partial or total amnesia for what has occurred.

The rarity of the syndrome can lead to diagnostic difficulties. It may not be recognised until several attacks have occurred, especially since the overeating is often not apparent to the patient. Other causes of morbid somnolence are likely to be diagnosed and a primary emotional disturbance may easily be suspected. Disturbed behaviour may dominate the picture, suggesting that the essential problem is a personality disorder or even schizophrenia. When circum-

stances prevent the patient from taking to bed he may become slovenly, unkempt and very erratic in conduct, as in the following case reported by Robinson and McQuillan (1951).

An army officer cadet of 19 came to the notice of the army doctors in an abnormal mental state. He was unkempt, offhand, casual and disinterested, answering vaguely and smiling fatuously. Affect was shallow and inappropriate and he experienced auditory hallucinations. He was clearly confused, cerebration was slow and there was evidence of thought blocking. In hospital he was hostile and insolent. Behaviour was often bizarre and he masturbated openly, grinning broadly. He slept a great deal and his appetite could not be satisfied. After 4 days in hospital the disturbance cleared abruptly, and he again became smart, respectful and well mannered. He was amnesic for the events of the previous days, though he realised that he had behaved badly and had been unable to control himself.

A history was then obtained of previous attacks, 2 years and 3 years earlier, each lasting several days and accompanied by somnolence and excessive hunger. In the first he had become strange and distant, avoiding company and seeming unaware of what was said to him. On two successive nights he had micturated into a pair of gumboots. He had sold a bicycle for 25 shillings and spent the money on preserved fruits which he consumed at one sitting. In the second attack he again became drowsy and with an insatiable appetite, and created much disturbance with laughing and shouting. After each attack he had returned abruptly to his normal personality.

Follow-up suggests that in the majority of cases attacks gradually lessen in duration, frequency and severity over several years and ultimately cease. The median duration of the disease in Annulf *et al.*'s series (2005) was 4–8 years. However, most case reports do not fit the classic description and in some cases the diagnosis is not justified. It is unknown how many chronic cases are incorrectly diagnosed.

Amphetamines have been claimed to reduce the frequency and severity of the attacks (Gallinek 1962). Lithium proved remarkably effective in preventing attacks in a typical example of the syndrome, with recurrence immediately when the drug was withdrawn (Ogura *et al.* 1976). Similar success with lithium has also been reported in periodic hypersomnia unaccompanied by appetite changes (Abe 1977; Goldberg 1983). Annulf *et al.* (2005) found a 41% response rate for stopping relapses compared with medical abstinence (1%). Neither, Carbamazepine nor other antiepileptics are effective.

Patients with secondary Kleine–Levin syndrome are older and experience more frequent and longer episodes, but have

clinical symptoms and treatment responses similar to primary cases. The disease usually lasts longer in female patients, with less frequent episodes during the first year (Annulf *et al.* 2005).

The cause is not known. Physical and mental health are usually normal between attacks, and few patients have shown evidence of significant maladjustment. Discernible precipitants can rarely be discovered for individual attacks. The similarity between one case and another and the uniform course pursued both suggest an organic basis. Diencephalic dysfunction is suggested by the combination of sleep and appetite disturbance. There has been only one possible familial case report: a pair of siblings who experienced uncharacteristically prolonged episodes of sleep and who also coincidentally shared HLA-DQB1*0602, the haplotype usually associated with the narcoleptic syndrome. However, CSF orexin (hypocretin) was normal when tested during an attack in one of the siblings (Katz & Ropper 2002).

Movement disorders during sleep

Hypnic jerks at sleep onset are a normal phenomenon and occur only during the early stages of sleep. A hypnic jerk is usually a single asymmetric body twitch, sometimes accompanied by a perception of falling, a vivid dream or hallucination, a sharp cry or a sensory flash. Oswald (1959) considered that hypnic jerks were part of an arousal response to minimal stimuli. They are increased by prior physical work, emotional stress and caffeine and reduced by alcohol and hypnotics. Their apparent association with anxiety may be due to heightened recall and difficulty falling asleep when anxious. Hypnic jerks are not related to other forms of myoclonus or epilepsy and no EEG or clinical abnormality has been associated with them.

The waking involuntary movements of extrapyramidal disease may be modified by sleep. During sleep the reduction in awareness, the loss of voluntary motor control and the diminution of muscle tone result in a reduction or abolition of the spasticity and rigidity of pyramidal and extrapyramidal disease. In Parkinson's disease, tremor may persist but only during stages 1 and 2 of NREM sleep and gross body movements are reduced by sleep. The non-rhythmic involuntary movements and abnormal postures of choreoathetosis and dystonia may partly disappear during deep sleep but return during REM. The multiple tics of Gilles de la Tourette's syndrome occur throughout sleep in all stages, including REM as well as NREM sleep. Epileptic discharge rates may be constant across all sleep stages, although the convulsive movements may diminish in intensity with the atonia of NREM and REM sleep. Different forms of myoclonus show varied changes during sleep.

Restless legs syndrome and periodic limb movement syndrome

Restless legs syndrome was clearly defined by Ekbom (1945) but had been described much earlier and was probably

known in ancient times. It usually presents as a sensory complaint, with deep, creeping, unpleasant or unbearable dysaesthesiae, sensations of cold, discomfort or weakness, usually most pronounced in the calves. It is accompanied by the irresistible desire to move the legs and the inability to keep them still. The restlessness is most common in the evening and is most severe before sleep onset and may persist into light sleep. The restless legs syndrome has close similarity to the whole body restlessness induced by neuroleptic drugs. However, sensory discomfort and motor 'impatience' are prominent in restless legs syndrome but not in akathisia. Whilst the legs and less commonly the arms are affected in restless legs syndrome, the whole body is usually involved in akathisia.

Rapid exercise, walking, leg rubbing or kicking may bring temporary relief. Curiously, symptoms may be abolished with fever. Severity usually increases with age, sleep deprivation and mental stress. It may commence or be exacerbated by pregnancy, CNS stimulants including caffeine, alcohol or antidepressant medication. It usually results in sleep-onset insomnia and consequently daytime sleepiness. The discomfort may be extreme and cause severe emotional disturbance. In addition, bed partners are at risk of being kicked or struck.

Many medical conditions have been associated with restless legs syndrome, including motor neurone disease, acute poliomyelitis, subclinical sensory neuropathy, amyloidosis, diabetes, anaemia, uraemia, malnutrition and various deficiency states. The age of onset varies, but it usually commences during the second decade. The course may be slowly progressive with wide fluctuations in severity. CSF hypocretin-1 levels were increased in subjects with restless legs syndrome, and were particularly high in subjects with early onset of the condition (Allen *et al.* 2002). There is a family history in up to 60% of cases and it may be transmitted as an autosomal dominant trait. Both familial and non-familial forms are very strongly associated with nocturnal myoclonus or periodic limb movement syndrome.

Periodic limb movement syndrome of sudden stereotyped limb movements throughout sleep is about three times more common than restless legs syndrome. The rhythmic repetitive movements are brief (0.5–5 seconds) and occur at regular 20–40 second intervals throughout the night. The repetitive muscle contractions last several minutes to an hour or more. The frequency and severity vary on different nights and physical and emotional stress make the condition worse. The jerking does not occur at sleep onset and is confined to NREM sleep. The movements are independent of other body movements during sleep and do not occur during waking. It affects 2% of the elderly population but up to 15% of patients investigated for insomnia. Although patients may be unaware of arousals caused by sleep myoclonus, sleep disturbance is common, with increased awakenings, decreased stage 4 NREM and complaints of both insomnia and excessive daytime sleepiness. Onset is

rarely before middle age and the prevalence increases with age.

Jerking must be differentiated from myoclonus with epilepsy as well as jerking and restlessness in sleep apnoea. Electromyographic monitoring may help to confirm the diagnosis. Good sleep hygiene is important. A warm bath at bedtime, gentle stretches of the leg muscles and relaxation tapes before sleep onset may be helpful. Some patients obtain benefit from the use of dopaminergic drugs.

Hypersomnias due to identifiable organic disease

The hypersomnias seen with overt cerebral or metabolic disease differ from the syndromes described above in many respects. They are rarely episodic and lack the transient and overwhelming nature of the narcoleptic attack. Sustained drowsiness is characteristic, or periods of sleep greatly in excess of normal requirements. Sometimes sleep inversion is seen with agitated delirium at night. In contrast to many cases of narcolepsy, the sleep of such hypersomnias does not refresh. Depending on the responsible pathology the patient may be roused with ease or difficulty, and to varying levels of alertness. The sleep is usually undisturbed and vivid dreams are rare.

Lesions involving the midbrain tegmentum or posterior hypothalamus are a common cause. The responsible pathology may be a tumour, vascular lesion or degenerative process. Excessive hunger and weight gain may be seen with the somnolence of hypothalamic lesions, likewise polyuria and polydipsia. Prolonged hypersomnia may follow encephalitis lethargica, general paresis or cerebral oedema from any cause. After head injury a variety of sleep disturbances can be seen, including excessive daytime somnolence and sleep apnoea syndromes (Guilleminault *et al.* 1983). These may cause significant disability and raise medicolegal problems. Infective processes such as encephalitis, typhoid, trypanosomiasis or tuberculous meningitis are regularly accompanied by somnolence. Guilleminault and Mondini (1986) have reported patients with prolonged and disabling daytime sleepiness following infectious mononucleosis.

Metabolic disorders such as uraemia occasionally present with somnolence, similarly the encephalopathies associated with anoxia, chronic respiratory insufficiency or hepatic disorder. Endocrine causes include hypothyroidism, Cushing's and Addison's diseases, diabetes mellitus and hyperinsulinism. Rarer causes are industrial toxins and lead encephalopathy. Abed and Bhalla (1991) have reported cases of prolonged hypersomnia following the administration of combined oral and depot neuroleptics, persisting for several months after discontinuation.

Sometimes organic hypersomnias are accompanied by psychiatric symptomatology, chiefly neurasthenic or depressive pictures. A patient described by Roth (1980) showed periodic hypersomnia and manic-depressive psychosis following a head injury, the hypersomnia phases accompa-

nying the depression; while depressed he slept for 20 hours per day, while hypomanic for 3 or 4 hours per day.

The EEG in such conditions generally shows the picture of sleep together with various anomalies in the form of diffuse slow components or bursts of bifrontal or generalised slow waves. The cyclic organisation of REM and NREM sleep is often modified or disrupted.

Insomnia due to organic disease

Insomnia following cerebral lesions has very occasionally been described. Bricolo (1967) reported a patient who developed total insomnia for 96 hours following bilateral stereotactic thalamotomy for Parkinson's disease. Thereafter he showed inversion of the sleep-wake rhythm which very gradually became more regular.

A remarkable post-traumatic example was described by Webb and Kirker (1981). A 33-year-old woman still showed severe insomnia 2.5 years after a relatively mild head injury. On some nights she claimed she did not sleep at all, while on others she slept for about an hour. In the evenings she felt exhausted but not somnolent. EEG and polygraph recordings on four consecutive nights supported her story, showing brief light sleep for less than an hour and no REM sleep. Hypnotics and sedatives were ineffective in doses that left her alert the following day. Nevertheless, four consecutive nightly doses of L-5-hydroxytryptophan, the precursor of serotonin, were dramatically effective, restoring normal sleep that persisted during several months' follow-up. In the absence of further examples it is hard to interpret such a response, though it remains possible that the drug served to trigger normal sleep mechanisms in the presence of some discrete brainstem lesion.

Fatal familial insomnia is an extremely rare disorder, consisting of progressively worsening insomnia with impairment of autonomic and endocrine functions, and motor signs including dysarthria, ataxia, myoclonus and pyramidal disturbance (Lugaresi *et al.* 1986; Medori *et al.* 1992a). It is inherited as an autosomal dominant with onset in middle age. The sleep disorder is characterised by reduction or loss of both slow-wave and REM phases of sleep. Over several months confusion and complex hallucinations ('enacted dreams') give way to progressive memory loss and impairment of consciousness. Death follows a period of coma 6 months to 3 years from the onset. Neuronal degeneration and astrocytosis are most pronounced in the anterior ventral and dorso-medial nuclei of the thalamus, but can extend to other thalamic nuclei, the olives, and the cerebral and cerebellar cortex. Spongiosis is occasionally observed and DNA analysis has shown mutations in the prion protein gene (Medori *et al.* 1992a,b).

Hypersomnias associated with psychiatric disorder

Most studies of patients with hypersomnia reveal cases in which psychological factors are clearly of aetiological impor-

tance. However, the proportion varies according to the orientation of the observer. Roth (1980) points out that during the nineteenth century most hypersomnias were thought to be emotional in origin, but then organic causes and clear-cut syndromes such as narcolepsy came gradually to be delineated. It still remains uncertain what proportion of cases have a definite psychological causation, as opposed to prominent psychological accompaniments to some other definable cause. Mixed patterns can present especial difficulties, since many of the recognised syndromes described above are strongly influenced by prevailing mood and environmental factors.

The nosology as well as the prevalence of psychogenic hypersomnias remains unclear. In the course of accumulating 88 narcoleptics, Sours (1963) found seven patients with hypersomnia that was symptomatic of organic conditions and 20 with hypersomnia attributable to psychiatric disorder; of the latter, nine were regarded as neurotic in origin, two as depressive reactions, two as hysterical and seven as schizophrenic. Smith (1958) suggested that most reported cases of psychogenic hypersomnia would be labelled more accurately as hysterical trances or psychotic stupors.

All agree that hysterical dissociation and depression are the major factors in well-marked examples, with a frequent theme of withdrawal from conflict-laden situations. The somnolence may set in abruptly after traumatic events or emotional upheavals, persisting thereafter for hours or days, or the condition may present recurrently over many months or years.

The following examples almost certainly reflect hysterical mechanisms at work.

One remarkable report concerned a patient who slept for 32 years, but during that time she cried when hearing bad news, would allow only certain persons to attend her, and was heard occasionally to speak (Froderstrom 1912).

A woman of 49 had a history of sleeping attacks for a year, sometimes lasting 36 hours at a time. Hysterical conversion features were present and became intensified during somnolent phases. When confronted with painful topics from her past life, drowsy attacks could be precipitated, but if caught in time and persuaded to expose the conflict-laden material she would return to normal alertness within minutes. She had had an incestuous relationship with her father and had also had a lover throughout her married life. 'Confessional catharsis' led to a great lessening of attacks in the years that followed (Spiegel & Obernborf 1946).

Depressive rather than hysterical mechanisms may have been operative in the following patient.

A 31-year-old teacher had suffered meningoencephalitis at 3 and was widowed at 22. From the age of 30 she frequently felt ill and suffered from headaches and giddiness when upset. After a 10-year relationship she broke off her engagement saying that her fiancé was not sufficiently well educated. After this she claimed to have slept for a whole week. Since then she had often fallen asleep, sometimes against her will and usually for a whole day. This always occurred after an emotionally upsetting experience. She ultimately improved with psychotherapy and light sedation (Roth 1980).

Hysterical states of somnolence will usually differ in several respects from true sleep. The patient may be unrousable even to painful stimuli, or show gross hysterical stigmata. The prolonged maintenance of certain postures, eyelid tremor, increased muscle tension or contraction of the masseters may be in evidence. EEG recordings made during such states may show wakefulness, perhaps even greater desynchronisation than usual, with a preponderance of fast activity and a good deal of muscle artefact.

Depressive hypersomnias, in contrast, may consist of long periods of genuine sleep; hence the difficulties that may be encountered in reaching a firm diagnosis. It is well recognised that hypersomnia may accompany depression or be the presenting feature (Detre *et al.* 1972; Kupfer *et al.* 1972; O'Regan 1974). In depressive hypersomnias attacks will rarely extend beyond 24 hours at a time, the posture during sleep will be normal and rousing will usually be possible. However, many so-called depressive hypersomnias may represent examples of Roth's 'idiopathic hypersomnia' accompanied by depression.

Patients who display negativism, *flexibilitas cerea* or other catatonic phenomena in the absence of extrapyramidal disease will be suspected of psychotic illness, either affective or schizophrenic in nature.

Unfortunately, few modern laboratory studies appear to have been carried out on patients with psychogenic hypersomnia. These would seem essential in working towards adequate differentiation between cases that rest on organic or pathophysiological factors and those which are primarily due to psychological causes. In the mean time, it is necessary to evaluate each patient as fully as possible for neurological and psychiatric disorder. It can be helpful to consider the following aspects individually (Roth 1980):

- determination from clinical observation of whether or not the attacks represent genuine sleep;
- evaluation of the course, whether static over years or intermittent, and the effect of external factors upon it;
- exclusion of any possible organic cause;
- assessment of the personality for evidence of pre-existent abnormalities;

- the mounting of combined EEG and polygraphic studies, wherever possible during attacks.

Where psychiatric factors appear to be causative, their alleviation may be decisive in clarifying the diagnosis. Treatment with stimulant drugs carries obvious hazards in any patient whose hypersomnia is due to psychological disturbance.

Somnambulism

Sleep-walking occurs predominantly in males. There is frequently a family history of the disorder and an association with enuresis. The great majority of cases occur in children, and the rare examples coming to attention in adult life are often among servicemen or men under indictment for an offence carried out during an alleged sleep-walking spell. Some 15% of children are alleged to have at least one sleep-walking episode, compared with 2–5% of the adult population (Kales *et al.* 1987).

Behaviour during the somnambulistic episode may sometimes consist of no more than sitting up in bed and making banal repeated movements for a minute or two. More prolonged examples consist of walking aimlessly about, or more rarely running, jumping or searching for something. In the main the behaviour is simple and stereotyped. The subject has a blank expression and movements tend to be repetitive and purposeless, though investigatory eye movements may be apparent and dangerous obstacles are usually avoided. Self-injury is rare but serious examples have been reported. Typically the subject behaves as though indifferent to the environment, with low levels of awareness and reactivity. However, if spoken to he may answer monosyllabically. Some are suggestible during the episode and carry out simple commands.

There is disagreement about the level of motor performance and dexterity that can be observed. Fenwick (1990), for example, states that acts can appear to be purposeful, directed and coordinated. The subject may dress or partially undress, open and shut doors and put himself seriously at risk. Cases have been reported in which patients have walked onto fire escapes or allegedly driven cars in a somnambulistic state. The question of violence during sleep-walking is considered further below.

Most attacks last for less than 10 minutes though some may last for half an hour or more. Spontaneous awakening sometimes occurs, but usually the subject returns to bed and continues normal sleep. Attempts at arousal result in gradual return to full awareness, often with marked disorientation and sleep drunkenness. Dream recall is not reported, and there is usually complete amnesia for what has transpired.

In children, sleep-walking is usually a benign condition, outgrown in later childhood, suggesting that it rests on delayed cerebral maturation. In a retrospective analysis, Kales *et al.* (1980) showed that when the onset was before the age of 10 years it was usually outgrown by 15. However, the

cases which come to attention in adult life appear frequently to be associated with severe psychopathology. Sours (1963) studied 14 patients aged between 17 and 27 referred from US Air Force bases. In most the disorder had begun at the time of puberty, and persisted thereafter with attacks every 1–4 months. Traumatic psychological events had seemed to precipitate the onset in many cases: parental death or divorce, a change of school or the birth of a sibling. In some patients each episode was precipitated by interpersonal tensions or other emotional problems. There was strong evidence of disturbed family backgrounds and difficult relationships with the parents. The majority had a past history of acting out behaviour, delinquency and thefts, and many showed evidence of anxiety, depression or depersonalisation. Hysterical conversion symptoms were common. Of the 14 patients, five were diagnosed as schizophrenic and four others were markedly schizoid in personality. The remainder were regarded as having character disorders.

Kales *et al.* (1980) similarly found that 29 adults with a present history of sleep-walking showed high levels of psychopathology on the Minnesota Multiphasic Personality Inventory (MMPI), whereas 21 who had outgrown it had essentially normal patterns. In the former, the sleep-walking had begun later, was more frequent and had more intense manifestations. However, it is difficult to know how typical these results may be of adult sleep-walkers generally.

The cause of somnambulism remains unclear. An explanation in psychodynamic terms was previously favoured, especially where episodes had an apparent purpose and the content was explicable in terms of current conflicts. The sleep-walking was then viewed as a dissociative state, similar to the hysterical fugue. It is now apparent, however, that sleep-walking rests on an abnormality of the sleep mechanisms of the brain and represents partial arousal out of the deep NREM stages of sleep. It occurs most often during the first third of the night when stages 3 and 4 predominate, stages during which dreaming is least likely to occur. Kales and Kales (1974) review laboratory studies confirming this in children, and running counter to the popular notion that sleep-walking represents the acting out of a dream. Episodes could sometimes be induced by lifting somnambulists to their feet during NREM sleep, whereas this did not provoke attacks in children not subject to the disorder.

An organic basis for sleep-walking has been established by the demonstration of a genetic association of the condition with HLA-DQB1 genes. A significant excess in transmission was observed in familial cases of somnambulism for the DQB1*05 and DQB1*04 haplotypes. This suggests that a DQB1 polymorphic amino acid might be more tightly associated than any single allele. This recent finding may implicate the HLA-DQB1 genes in disorders of motor control during sleep generally since specific DQB1 genes are also associated

with narcolepsy and REM behaviour disorder (Lecendrex *et al.* 2003).

Conditions that predispose to higher levels of slow-wave sleep, such as sleep deprivation, shiftwork or alcohol consumption, can be expected to increase the frequency of sleep-walking (Driver & Shapiro 1993). It may be commoner during periods of stress and anxiety. Attention has also been drawn to the liability of certain drugs, taken at bedtime, to induce somnambulism in susceptible individuals (Huapaya 1979; Nadel 1981). Hypnotics, neuroleptics, antidepressants, tranquillisers, stimulants and antihistamines have been incriminated, often in combination and sometimes when taken with alcohol. Luchins *et al.* (1978) reported an example, apparently induced by thioridazine and a derivative of chloral hydrate, during which a 44-year-old psychotic woman stabbed her daughter to death. Sleep laboratory studies confirmed the liability of thioridazine to lead to sleep-walking in this patient, which occurred repeatedly out of stage 4 NREM sleep.

The question of violence towards others during sleep-walking can raise important medicolegal issues and such a defence not uncommonly comes before the courts. Simple aggression usually results from the terror and disorientation of partial arousal from deep slow-wave sleep (Parkes 1985). More difficulty is encountered when weapons have been employed or purposeful coordinated behaviour has been implicit in the act. Oswald and Evans (1985) described a 14-year-old boy who stabbed and severely injured his 5-year-old cousin with a knife, and Fenwick (1987, 1990) reviews other examples from the literature where violence has occurred. Sleep-walking may also be put forward as a defence against sexual assault.

In appraising such cases, Fenwick (1987, 1990) points out that a family history and childhood history of sleep-walking greatly increase the chance that the episode in question is genuine. A first episode occurring in adulthood should be viewed with suspicion. Consequently, it is vital to establish the authenticity of an apparent history of childhood sleep-walking. Genuine sleep-walking is most likely to occur within 2 hours of sleep onset; any witnesses are likely to report inappropriate automatic behaviour, usually with an element of confusion, and there will be substantial amnesia for what transpired. Trigger factors such as drugs, alcohol, excessive fatigue and stress will often feature in the episode. Attempts to conceal the crime will be unusual, the natural response on waking being to summon help immediately. It is helpful if the offence can be shown to be motiveless and out of character for the individual. When there is a sexual element in the offence, careful enquiry should be made for sexual arousal with penile tumescence, since its presence would make a sleep automatism highly unlikely.

In the past sleep-walking has been regarded by the law in England and Wales as a 'sane automatism', leading to acquittal when successfully raised as a defence. However, in the

case of *R. v. Burgess* (1991), it was agreed that since somnambulism has a genetic cause and arises from internal factors (i.e. a specific stage of sleep) it should be regarded as an 'insane automatism' and likely to recur (Fenwick 1990). Previously, a verdict of insane automatism inevitably led to detention in a psychiatric hospital. However, since the Criminal Procedure (Insanity and Unfitness to Plead) Act 1991 discretion may be exercised by the court as to the appropriate disposal. This may take the form of a supervision and treatment order. Somnambulism is still regarded as a sane automatism in some jurisdictions.

With regard to treatment, the most important factor is protection from injury. Doors and windows should be locked and dangerous objects removed. Patients should be advised to avoid situations leading to sleep deprivation and to avoid taking alcohol before going to bed. Psychiatric treatment is rarely indicated in children, since most outgrow the disorder and in any case are not markedly disturbed. In adults, however, full psychiatric evaluation and treatment may be required. In persistent cases drugs such as diazepam or flurazepam, which suppress stages 3 and 4 of NREM sleep, may warrant a trial (Kales *et al.* 1987). Their effectiveness has been more convincingly shown with night terrors, discussed immediately below.

Night terrors

Night terrors also arise out of stages 3 and 4 of NREM sleep, differing sharply in this respect from nightmares which occur during phases of REM sleep (Rechtschaffen *et al.* 1963; Kales & Kales 1974). Night terrors and sleep-walking often occur in the same individual and a family history of both is common. Kales *et al.* (1980) suggest that the two form a continuum, with sleep-walking the mild end and night terrors the more extreme end of a spectrum. The usual time of occurrence is within an hour or so of going to sleep. Episodes are rare after the middle of the night, because stages 3 and 4 of NREM sleep become shorter later on.

The episode is accompanied by intense anxiety, autonomic discharge, vocalisations by way of screams, moans and gasps, a racing heart and panting respiration. It typically lasts for only a few minutes and the patient is usually amnesic for the event thereafter. If any content is recalled, this is usually limited to a single frightening image of being attacked, choked or crushed (Oswald & Evans 1985). Occasionally, destructive acts may be carried out such as slashing at objects or hitting other persons (Fenwick 1987).

Follow-up studies show that most children outgrow the disorder in later childhood. As with somnambulism, psychological disturbance is common in affected adults but not in children. Daytime anxiety is also high in adults with the disorder. Diazepam and flurazepam are effective in diminishing night terrors, both in children and in adults. Propranolol can also be markedly beneficial (P. Fenwick, personal communication).

REM sleep behaviour disorder

Schenck *et al.* (1986) and Schenck and Bundlie (1987) have identified a form of acute behavioural disturbance occurring during sleep which, unlike somnambulism or night terrors, emerges during the REM phases and represents the acting out of altered dreams. This has been confirmed by polysomnographic studies. It seems that in these patients the normal inhibitory outflow from pontine centres to the spinal motor neurones during REM sleep is diminished, allowing motor behaviours to emerge (see Fig. 13.4).

Typically the patient develops a progressive sleep disorder, with the abnormal behaviours appearing during the middle or final third of the night and almost always more than 60–90 minutes after sleep onset. The episodes characteristically occur during nightmares of being chased or attacked. Concurrently there has usually been a change in the nature of the dreams experienced, which come to involve motor overactivity and violent confrontations with dream characters. The patient talks, shouts or jumps out of bed during sleep, often injuring himself or grabbing at others in a frenzied or aggressive manner. Such behaviours often clearly represent the attempted enactment of dream material.

A 52-year-old salesman of placid temperament began to talk, yell and sit up during sleep. After 2 years he began to punch, kick and jump out of bed between one and seven nights weekly, often striking and bruising his wife and once punching through a wall. These episodes, which always occurred at least 2 hours after sleep onset, were often the enactment of dreams that had become more vivid, action-filled and violent. 'Usually something is scaring me or is going to hurt my family and I try to protect them. Then I get most violent.'

A 67-year-old man developed a progressive sleep disorder in conjunction with a dementing illness. Limb jerking, moaning and talking appeared every night, with episodes of punching, kicking and running into furniture. On one occasion his wife saw him throw punches while he dreamed he was fighting squirrels in an attic. Both he and his wife had received numerous injuries during sleep (Schenck & Bundlie 1987).

Schenck and Mahowald (1990) have reported 70 consecutive cases with a marked predominance among older males. The mean age at onset was 53, with a range from 9 to 73 years. Many had initially been suspected of nocturnal epilepsy, obstructive sleep apnoea or various psychiatric conditions. The majority were otherwise healthy, but one-third showed

Fig. 13.4 REM sleep without atonia in a patient with REM sleep behaviour disorder. Note the prominent muscle activity and body movements during REM sleep, which is normally accompanied by active muscle paralysis. EEG, electroencephalogram; EMG, electromyogram. From Mark W. Mahowald and Carlos H. Schenck (2005) Insights from studying human sleep disorders. *Nature* **437**, 1279–1285.

evidence of a causal association with CNS disorders such as dementia, Parkinson's disease, narcolepsy, or occasionally vascular or other brainstem lesions. In some cases there was an apparent association with drug or alcohol withdrawal, or the condition set in after major stressors. In most cases the disorder proved to be gradually or rapidly progressive up to the time of treatment. Three-quarters of the subjects had sustained repeated injuries, mostly bruises or lacerations but extending occasionally to fractures or dislocations.

Schenck and Mahowald (1992) have reported additional cases in narcoleptic patients, these appearing to represent almost 12% of the narcoleptics undergoing polysomnographic studies in their clinic. Treatment with stimulants or tricyclic antidepressants had sometimes induced or exacerbated the condition. Curiously, REM behaviour disorder is associated with HLA-DQw1, a supertype of DQB1*0602 associated with the narcoleptic syndrome (Schenck *et al.* 1996).

Polysomnographic studies show preservation of the usual distribution and cycling of sleep stages, though sometimes with reduced REM latency, increased REM density and increased stage 3 or 4 sleep. Periodic and aperiodic limb twitching is common during NREM sleep. The defining characteristic, however, is intermittent loss of the normal electromyographic atonia during REM phases. Seizure activity was never detected in Schenck and Mahowald's cases.

Treatment with clonazepam was rapidly effective in controlling both the disturbing dreams and the problematic sleep behaviours, with only infrequent and minor lapses

thereafter. Previous treatments with a variety of sedative-hypnotic drugs had not been helpful. Alternative treatments include desipramine, carbidopa and clonidine, and these can be of value in patients with sleep apnoea where clonazepam may be contraindicated.

Other Disorders of the Nervous System

Simon Lovestone

Institute of Psychiatry, King's College, London

Several disorders of the nervous system not falling within the province of the foregoing chapters remain to be considered. Attention is restricted to those which have attracted some degree of psychiatric interest, either on account of the psychological, cognitive or behavioural symptoms that accompany them or because they can raise problems of differential diagnosis in the overlap between neurology and psychiatry.

Patients with neurological disease sometimes first come before the psychiatrist, usually at an early stage and before there is unequivocal evidence of central nervous system (CNS) pathology. The incidence of erroneous diagnoses is hard to assess but the findings of Tissenbaum *et al.* (1951) may not be unrepresentative even today. On reviewing approximately 400 neurological patients attending a Veterans Administration clinic, they found that 53 (13%) had been considered to suffer from a psychiatric disorder before the neurological diagnosis was established, the commonest psychiatric diagnoses being conversion hysteria, neurosis or affective disorder. The situation was particularly common among patients with Parkinson's disease or multiple sclerosis. In some instances organic disease had been suspected for some time, although the suspicion of non-organic psychiatric disorder persisted until the underlying disease had progressed much further.

In some neurological disorders psychiatric symptoms are an integral part of the disease process, representing the direct effects of CNS involvement on mental functioning. This is most clearly discerned in the numerous disorders that can lead to cognitive impairment, but cerebral pathology may also play a part in determining subtle changes of personality, disorder of affect or even psychotic developments. Where there is evidence on such matters this is discussed. Other psychiatric disturbances in neurological disease have little to do directly with brain pathology, but reflect the reaction of the patient to his disablement. Neurological disability can

pose severe threats to independence and security, or provide obstacles to free communication. Not unnaturally these may tax the individual's capacity for psychological adjustment over time. Emotional symptoms and even frank mental illness may then result, and owe their origin predominantly to the patient's problems and aspects of his social situation. Sometimes, of course, both organic and non-organic factors will be operative together. The correct appreciation of such matters is an essential prelude to planned intervention and help and the neuropsychiatrist and the liaison psychiatrist have an important, and increasingly recognised, role to play in the management of patients with chronic neurological disease and disability.

Some of the disorders considered below are not uncommon. Others are very rare, but can nonetheless be important in the present context if they are liable to have marked psychiatric sequelae.

Multiple sclerosis

Multiple sclerosis (MS) is by far the most frequent of the demyelinating diseases, and indeed is one of the commonest diseases of the nervous system in temperate climates. It is particularly common in the northern hemisphere but rare in tropical and subtropical regions. Although the actual incidence is low, the chronicity of the disorder leads it to rank as a major cause of disability.

The aetiology remains unknown despite a large amount of research and a number of tantalising clues. At various times causative theories have involved vascular, infective, dietary and metabolic mechanisms but none can be considered well established. The present consensus is that the disease results from an interplay between genetic and environmental factors, resulting in an immunologically mediated inflammatory response within the CNS. Two very large studies have shown that the most important genetic susceptibility

factors are within the human leucocyte antigen (HLA) class II region of the major histocompatibility complex (MHC) (Lincoln *et al.* 2005; Sawcer *et al.* 2005). Although the data for association with this region are very strong and other regions of the genome are unlikely to play significant effects on aetiopathogenesis, the association is not simple and epistatic effects and interactions with other genes, perhaps with other regions of the MHC, appear to play important roles.

Three sources of evidence point to a strong effect of the environment: twin discordancy, migration studies and gradients in prevalence, especially comparing northern and southern hemispheres. Compston (1993) reviews data from Australia and New Zealand which indicate that living in the southern hemisphere is relatively protective. The environmental effect appears to exert its influence in adolescence, as place-of-birth risk is carried over in adult migrants but is similar to the acquired environment in child migrants. The 'hygiene' hypothesis postulates that the relatively disease-free childhoods of the developed world act to prevent the fullest development of the immune system and the frequent immunological challenges of early life in the less developed world are protective. Giovannoni and Ebers (2007) review recent evidence addressing this attractive hypothesis, including cohort and sibship studies, and find no evidence in favour and much to challenge the hypothesis. On the other hand, the evidence is growing that vitamin D, or exposure to high levels of sunlight associated with vitamin D generation, is protective and vitamin D supplementation may also offer some therapeutic protection against relapse (Brown 2006). Smoking increases risk of MS, with an odds ratio of 1.36 in a meta-analysis (Hawkes 2005). A variety of specific infectious agents have also been proposed as factors that increase risk. Of these the evidence is strongest for Epstein-Barr virus (EBV) (Giovannoni & Ebers 2007) as demonstrated by meta-analyses of case-control and cohort studies of people with EBV exposure, evidence for increased risk for MS in those with anti-EBV antibodies, an association between Hodgkin's lymphoma and MS, and some evidence for EBV activity in people with MS.

Clinical features

The onset is chiefly in young adults between 20 and 40 years of age. In the UK females are affected more often than males. The disorder is protean in its neurological manifestations, traditional diagnostic criteria laying emphasis on both the multifocal and relapsing nature of the symptoms and signs. Typically there is evidence, over time if not at a single examination, of disseminated lesions in the CNS, which at least in the early stages show a tendency to remission and relapse.

Early manifestations frequently include retrobulbar neuritis, disorders of oculomotor function leading to diplopia or nystagmus, or lesions of the long ascending or descending

tracts of the cord producing paraesthesiae or spastic paraparesis. Precipitancy of micturition may be an early symptom, likewise ataxia or intention tremor due to cerebellar involvement. Retrobulbar neuritis is particularly common and can occur as a transient disturbance antedating other manifestations by many years.

The initial symptoms tend to settle within weeks or months, sometimes disappearing completely but sometimes leaving residual disability. Further attacks bring new symptoms or an intensification of those already present. The interval between attacks is extremely variable but in exceptional cases remissions may last for 25 years or more. It is 8 years (median value) before patients experience limited walking ability, 20 years before they are able to walk no more than 100 m using unilateral aids, and 30 years before they can walk no further than 10 m (Vukusic & Confavreux 2007). Although these average figures are consistent, there is wide individual variation in natural history and, as yet, no reliable means of predicting prognosis. At presentation most patients show a relapsing-remitting disease course (RRMS) and almost all go on to have secondary progressive disease (SPMS). Some 10% show steady progression of disability from the outset (primary progressive MS). The latter is the usual mode of progression with onset after the age of 50 years. The least common presentation, affecting some 5% of patients, is progressive-relapsing MS (characterised by acute attacks superimposed on progressive decline). Ultimately, almost all patients show downward progression with an accumulation of multiple handicaps. In about one-fifth of cases the disease proves to be relatively benign in that there is minimal disability even several years from the onset. However, there can then be sudden deterioration after a period of remaining symptom-free. The outlook is generally better when purely sensory or visual symptoms have been the chief manifestations since the beginning, whereas disorders of motor coordination or balance confer a poorer prognosis. The most sinister development is the appearance of progressive disease, whether from the outset or after a number of relapses. Younger onset tends to result in a less aggressive form of the disease and the clinical courses, whether relapsing-remitting, primary progressive or progressive, are to a large degree age-related manifestations of the same disease process (Vukusic & Confavreux 2007).

On examination typical early pointers to the diagnosis include pallor of the temporal halves of the optic discs, nystagmus, mild intention tremor, exaggerated tendon reflexes, absent abdominal reflexes, extensor plantar responses, and impaired vibration and joint position sense. During early remissions of the disease, however, there may be little or nothing to detect by way of abnormal signs. Later there is evidence of multiple lesions particularly affecting the optic nerves, cerebellum, brainstem and long tracts of the cord. Eventually the patient is likely to show some combination of

ataxia, intention tremor, dysarthria, visual impairment, dissociation of conjugate lateral eye movements, paraparesis, sensory loss in the limbs and urinary incontinence. The psychological manifestations described below will emerge in a large proportion of cases, some being attributable to lesions in the cerebral hemispheres. Epileptic seizures are a rare manifestation, occurring in about 2% of cases.

There are no laboratory findings which are pathognomonic for the disease, but abnormalities occur in the cerebrospinal fluid (CSF) in a high proportion of cases. About half show a slight increase of mononuclear cells in the acute stages or a moderate elevation of protein. The γ -globulins are typically abnormally high, with the relative proportion of IgG selectively raised (Luque & Jaffe 2007). Electrophoresis of the CSF commonly shows the striking appearance of oligoclonal bands within the immunoglobulin fraction. However, false positives may occur with both of these tests. Other proteins have promising characteristics as biomarkers either for diagnosis or for monitoring progression, including neurofilament light chain and antibodies against the heavy chain (Teunissen *et al.* 2005; Luque & Jaffe 2007).

Halliday *et al.* (1973) made an important contribution by demonstrating the diagnostic value of visual-evoked responses in patients suspected of MS. Delayed forms of response from one or both eyes on the presentation of visual patterned stimuli have been shown to correlate highly with the diagnosis, even in patients without a history of optic neuritis and with normal optic discs on ophthalmoscopy. Clearly subclinical lesions of the visual pathways are very common in MS and can be readily detected with such a test. Brainstem auditory-evoked responses are also frequently abnormal. Somatosensory-evoked responses, recorded over the cervical spine while stimulating the median nerve at the wrist, can similarly detect subclinical abnormalities in the somatosensory pathways.

Neuroimaging in multiple sclerosis

Magnetic resonance imaging (MRI) has come to play a major role in the diagnosis of MS and in monitoring disease progression, not least in clinical trials (Arnold 2007). It is now apparent that almost all patients with clinically definite MS will show discrete white matter abnormalities on MRI, mostly periventricular lesions but also lesions in the optic nerve, brainstem and spinal cord. Brain atrophy is also a feature of disease and is most widespread in patients with large numbers of plaques. Grey matter shows more atrophy than white matter. Accumulated experience has shown that normal MRI of the brain all but excludes the diagnosis of MS (Armstrong & Keevil 1991). Conversely, the presence of multifocal circumscribed areas of altered signal with predilection for the periventricular regions will strongly suggest that the disease is present when clinical features are equivo-

Fig. 14.1 MRI scans showing plaques in the periventricular white matter in a patient with multiple sclerosis. (Reproduced from Hotopf, M.H., Pollock, S. & Lishman, W.A. *Psychological Medicine* (1994), **24**, 525–528, courtesy of Cambridge University Press.)

cal (Fig. 14.1). MS plaques visible on MRI as T2-hyperintense lesions are typically oval in shape, 5 mm or larger in size and are more often to be found in white matter than grey matter (Neema *et al.* 2007). Although some of these lesions resolve over time, most persist. MRI techniques have been developed that are more sensitive than conventional T2-weighted images, including fluid-attenuated inversion recovery (FLAIR) and double inversion recovery (DIR). These approaches are particularly useful in detecting grey matter lesions (Bakshi *et al.* 2001; Pirko *et al.* 2007).

Serial studies in individual patients have shown that the earliest change in an evolving plaque is an increase in permeability of the blood–brain barrier, shown by areas of enhancement with gadolinium-diethylenetriaminepentaacetic acid (DTPA) (Bruck *et al.* 1997). Gadolinium enhancement reflects an early stage in plaque development and can distinguish active lesions from those that have been present for many years.

The criteria for diagnosis of MS include T2-hyperintense lesions and gadolinium-enhancing lesions both for primary diagnosis and for dissemination (Arnold 2007). Thus a

change in MRI findings can substitute for clinical symptoms as evidence for dissemination in time as well as dissemination in space (McDonald *et al.* 2001; Polman *et al.* 2005). MRI can be invaluable in making treatment decisions in MS (Arnold 2007).

Proton magnetic resonance spectroscopy (MRS) in MS reveals decreased *N*-acetylaspartate in white matter in the absence of plaques, and elevated choline, myoinositol and lipids (Neema *et al.* 2007). Some evidence suggests stronger correlations between MRS measures and clinical features including both symptoms and prognosis. Other approaches showing promise as MRI-based markers include magnetisation transfer imaging (MTI) and diffusion tensor imaging (DTI), both of which may reveal disease in plaque-free areas and both of which may function as markers of response to putative therapies (Neema *et al.* 2007).

Pathology

The pathological changes within the nervous system consist of scattered sharply circumscribed areas of demyelination and degeneration of long axonal tracts. The blood–brain barrier shows evidence of breakdown and there is widespread evidence of inflammation, gliosis, loss of oligodendrocytes and axonal degeneration. The inflammatory response includes both innate and adaptive immune responses and is directed at both myelin itself and at oligodendrocytes (Dhib-Jalbut 2007; McQualter & Bernard 2007). This autoimmunity probably results from a response of the peripheral immune system being exposed to antigens normally preserved behind the blood–brain barrier but the mechanism for this remains unknown. Moreover, although autoreactive T cells are an invariable component of disease, their induction alone is insufficient to generate a full blown autoimmune disease which must result from other factors combining with autoreactive T-cells and resulting in a complex immune reaction or cascade (McQualter & Bernard 2007).

Macroscopically, the plaques show as greyish translucent areas which may be found in all parts of the neuraxis, chiefly in the white matter but sometimes also in the grey matter of the cortex and spinal cord. Typically, the number of lesions greatly exceeds what would have been expected from the clinical findings. The cerebellum and the periventricular areas of the hemispheres are sites of special predilection.

Microscopically, the acute lesions show degeneration of the myelin sheaths while the axis cylinders remain intact. The perivascular spaces contain lymphocytes and macrophages laden with neutral fats. Later the damaged myelin disappears and astrocytes proliferate to form a glial scar. At this stage axonal destruction is observed within the plaque, although recent evidence demonstrates that axonal degeneration starts early and is a universal and persistent feature of the disease (Dutta & Trapp 2007). Axons may be damaged by

direct inflammatory attack, by the loss of myelin or by other mechanisms and the site of damage is in both grey and white matter (Dutta & Trapp 2007).

Treatment

The arrival of potential disease-modifying treatments for MS brings substantial hope to sufferers. However, the effect of approved therapies on disease progression has been relatively modest, although the effects of some interventions on the frequency of relapse, and on markers of disease, have been confirmed in large trials (Hemmer & Hartung 2007; Kleinschnitz *et al.* 2007). Interferon (IFN)- β delays conversion from a single demyelinating episode to clinically definite MS and is recommended for use early in the disease course in some countries. However, IFN is only partially effective and the majority of patients will still progress to full disease. Glatiramer acetate was approved for use in relapsing–remitting MS, although a large clinical trial found no benefits relative to placebo. Neither IFN- β nor glatiramer acetate are currently recommended for use in the UK by the National Institute for Clinical Excellence (NICE). Modulating the immune system by intravenous immunoglobulins was not supported by large studies, although plasma exchange may be of some benefit in people with particularly aggressive disease. A monoclonal antibody to $\alpha 4 \beta 1$ integrin, natalizumab, is approved in the USA and Europe for active relapsing forms of MS and is supported by NICE in the UK. In one trial 96% of patients treated with natalizumab showed absence of new gadolinium-enhancing lesions compared with 68% of placebo-treated patients and in another large randomised controlled trial the addition of natalizumab to IFN- β was shown to be beneficial in relation to both relapse rate and MRI markers of disease (Polman *et al.* 2006; Rudick *et al.* 2006a). Although currently approved, concerns remain about safety following the development of progressive multifocal leucoencephalopathy in two patients receiving both natalizumab and IFN- β (Kleinschnitz *et al.* 2007). Despite this, these two compounds are the first specific, molecularly targeted therapies for MS that have resulted from primary research and many other compounds are in development (Hemmer & Hartung 2007; Kleinschnitz *et al.* 2007).

Recovery from acute exacerbations of the disease is speeded by methylprednisolone, which probably acts by reducing brain oedema in areas of acute inflammation. Prednisolone may be given intravenously or by high-dose oral administration. Immune suppression can stabilise the course in patients with rapidly progressive disease, and a variety of immunosuppressive agents have been tried in attempts to improve the long-term outlook. Azathioprine and mitoxantrone, intravenous immunoglobulins and plasma exchange and short-course high-dose methylprednisolone are all recommended by NICE, albeit under strictly defined

circumstances (available at www.nice.org.uk). The NICE guidance also reviews recommendations for a wide variety of treatments for specific sets of symptoms in MS.

Psychiatric aspects

Neuropsychiatric symptoms are a core component of the MS phenotype and include disorders of affect and behaviour and cognitive symptoms. Attention has also been directed to the possibility that psychological factors may be associated with relapses of the disease. The historical development of psychiatric interest in the disorder is traced by Surridge (1969). Early investigators regarded intellectual deficits as the main disturbance, and towards the end of the nineteenth century there were numerous reports of acute psychoses occurring in the disease. However, many of these studies were made before MS could be adequately distinguished from cerebrovascular syphilis. Cottrell and Wilson's (1926) study then had an influential effect. In a consecutive series of 100 outpatients, they found that emotional changes were strikingly common, usually taking the form of increased cheerfulness and optimism. A sense of physical well-being was frequent among the patients despite their severely disabled state. In contrast to these affective changes, intellectual disorders were minimal or negligible. Brain (1930) added hysterical conversion symptoms as a further characteristic of the disease, suggesting that MS might predispose in some way to the mental dissociation responsible for hysteria. From then onward euphoria and hysteria continued to be emphasised in the English literature as typical of MS.

Meanwhile, Ombredane (1929) re-emphasised the occurrence of intellectual deficits. Disturbances of affect were common in the intellectually deteriorated cases, but consisted chiefly of rapid unstable variations in mood rather than constant shifts towards euphoria or depression. Runge (1928) maintained that depression occurred in the early stage but gave way to euphoria as the disease progressed further. Euphoria was seen simply as a concomitant of intellectual deterioration. This view, in sharp contrast to Cottrell and Wilson's findings, became prominent on the European continent thereafter.

More recent investigators have sought to resolve the dilemma by careful surveys of the psychiatric changes in large series of patients. Surridge's (1969) investigation was exceptional for its thoroughness, and in providing a control group suffering from a different progressive disease, namely muscular dystrophy. In this study, 108 patients suffering from MS were visited in their normal places of residence, and separate accounts were obtained from informants to aid in the assessments of mood, intellectual deficits and personality changes. The sample was considered to be representative of patients with MS, except for some possible bias towards more severely disabled cases.

Of the MS patients, 75% were found to suffer some psychiatric abnormality, compared with less than half of the controls. Intellectual deterioration was present in 61%, varying in degree from mild memory loss to profound global dementia. None of the controls showed intellectual impairment. Abnormalities of mood were found in 53% compared with 13% of controls; 27% were depressed, 26% euphoric and 10% showed exaggeration of emotional expression. Euphoria was almost exclusively seen in patients who were intellectually impaired, and a significant correlation emerged between increasing euphoria and increasing intellectual deterioration. Euphoria was also associated with denial of disability which was observed in 11% of the patients. Impaired awareness of disability short of complete denial was found in 31%. Of the MS patients, 40% showed personality change compared with 33% of the controls. This was predominantly a change towards irritability, whereas the muscular dystrophy controls often showed increased patience and tolerance. Psychotic disorders were rare.

These findings effectively set the stage for subsequent studies, which have increasingly used neuropsychological assessments and objective rating procedures for charting the changes observed. Control comparisons have amply confirmed the vulnerability of patients to a range of cognitive and emotional complications, as outlined below. However, considerable difficulties are encountered in reaching firm conclusions about the prevalence of psychiatric disorder in the disease in view of its widely varying manifestations. For example, Dalos *et al.* (1983) have shown that much depends on whether patients are studied during remissions or relapses; psychiatric symptoms, mainly anxiety and depression, were present in 39% of patients examined during stable periods and in 90% during exacerbations. Certain differences have also emerged between patients with relapsing–remitting and chronic forms of MS, particularly in relation to cognitive deficits (see below).

It can be uncertain how far psychiatric manifestations are attributable to brain pathology rather than representing psychological reactions to the threats and limitations imposed by the physical symptoms. Evidence can sometimes be found for a causal role of brain pathology even where seemingly non-organic symptoms such as depression are concerned, but other influences are also clearly at work. For example, Ron and Logsdail (1989) found that psychiatric morbidity in their sample was strongly related to the degree of social stress perceived by the patient. This suggests an interactional model whereby the vulnerability created by the presence of brain damage enhances the effects of environmental and personal factors in producing psychiatric disorder (Ron & Feinstein 1992). In seeking to define the organic contribution, recent studies have been greatly helped by the availability of sensitive brain-imaging techniques. These have also allowed exploration of the possible contributions of 'covert' brain lesions from early in the disease.

Cognitive impairment

Cognitive impairment occurs in 40–65% of patients with MS (McIntosh-Michaelis *et al.* 1991; Rao *et al.* 1991; Amato *et al.* 2006; Einarsson *et al.* 2006). Much is likely to depend on the stage of the disease at which assessments are made, but even so it is apparent that patients differ markedly in their liability to become impaired. This is perhaps not surprising since the accent of the disease can fall on very different parts of the neuraxis. The severity of impairments also varies widely, from those only detectable on careful testing to pictures of global dementia.

Some studies have found a relationship between cognitive impairment and severity of neurological disability while others have not. Peyser *et al.* (1980a) showed that cognitive deficits could be present or absent in groups with varying levels of disablement. Cognitive impairment may occur early (Ghaffar & Feinstein 2007) and it is clear that psychometric evaluation may reveal deficits that have gone unsuspected on more cursory examination. Peyser *et al.* (1980b) and Heaton *et al.* (1985) found that half of patients judged to be cognitively intact on routine examination were impaired on psychometric testing. In Heaton *et al.*'s study, 46% of relapsing–remitting and 72% of chronic progressive MS patients were found to show cognitive deficits. The progressive group was more severely impaired and on a wider range of functions.

Verbal skills are often relatively well preserved, which may account for other deficits being overlooked. The functions most markedly affected include memory and learning, and capacities to deal with abstract concepts and problem-solving. Attentional processes may be impaired from a very early stage and slowed information processing speed may be the most common cognitive deficit (Benedict & Bobholz 2007).

Memory impairment has been highlighted as one of the commonest deficits encountered, second only to decline in motor skills. Various studies indicate that 40–60% of MS patients perform below expectation on memory tests when compared with control groups (Grafman *et al.* 1991). Again, however, patients vary considerably, some being affected early in the disease while others remain unimpaired. Primary memory as reflected in the digit span appears to remain relatively intact, and rates of forgetting are also largely normal as measured by the Brown–Peterson task. Working, semantic and episodic memories are all affected (Ghaffar & Feinstein 2007). The role of attentional deficits in leading to such problems has not been fully explored, but both depression and psychotropic medication have been exonerated as a complete explanation.

Other cognitive processes emerge as defective in a substantial proportion of patients (Rao 1986; Benedict & Bobholz 2007). Language deficits are rare, except for reductions in verbal fluency. However, marked difficulties may be encountered with psychomotor efficiency and attention and concen-

tration. Problems with abstract thinking, conceptualisation and the shifting of sets may resemble those seen with frontal lobe injuries. Perseveration can sometimes be detected. Mahler and Benson (1990) draw an analogy with the pictures seen in ‘subcortical dementia’. Such difficulties can emerge in patients who score well on tests of general intelligence, and will then often go unsuspected. In occasional examples the picture amounts to a clinically recognisable dementia.

Thus it is apparent that some patients have not only to adapt to progressive physical disability, but must often do this against a background of diminishing intellect and impaired adaptive capacity. The implications for retraining are obviously important; the presence and severity of impairments such as these may well be crucial in determining the outcome of efforts at rehabilitation.

A consensus conference in 2001 led to the development of a battery of tests designed to detect and assess cognitive impairment in MS: the Minimal Assessment of Cognitive Function in MS (MACFIMS). This battery comprises seven tests covering the cognitive domains known to be affected including processing speed, working memory, episodic memory, verbal memory, executive function and others (Benedict & Bobholz 2007).

The course followed by cognitive impairments may be as variable as the neurological symptoms of the disease. Some patients experience relapses and remissions, while others show steady progression of their cognitive deficits. Attempts to chart the course of decline in patient groups have therefore yielded conflicting results (see Canter 1951; Ivnik 1978). In the first truly prospective study, Filley *et al.* (1990) found remarkably little evidence of progression in a group of 46 patients, only 6 of 36 test measures showing significant deterioration over 1–2 years. On global clinical ratings, however, 7 of 10 patients with chronic progressive disease showed worsening; of the 36 with relapsing–remitting disease, a smaller proportion showed deterioration and this was mainly evident on retesting during a documented relapse. Overall, approximately one-quarter of patients deteriorate, the prevalence of cognitive impairment increasing from 26% to 56% over 10 years and the degree of impairment increasing over this time (Amato *et al.* 1995, 2001).

The high prevalence of cognitive impairment is hardly surprising in view of the finding that plaque formation is widespread. Professor Ron and her colleagues have conducted a series of elegant MRI studies which show that even ‘subclinical’ brain involvement can lead to detectable cognitive deficits.

Callanan *et al.* (1989) investigated 48 patients with ‘clinically isolated lesions’ of the type seen in MS. Subtle cognitive deficits were already apparent. On MRI 80% of these showed cerebral abnormalities, by way of increased signal in the periventricular rim or discrete lesions in the brain parenchyma, and the extent of such abnormalities correlated with impairment on tests of abstracting ability and auditory attention.

Feinstein *et al.* (1992a) concentrated on tests of attention and speed of information processing in over 40 patients who had recently suffered a first episode of acute optic neuritis, and who in all other respects were neurologically normal. Approximately half of the sample showed abnormalities on brain MRI, and these were more impaired on the tests than patients without cerebral lesions or normal controls. Thus both studies demonstrated that cognitive deficits can be the only manifestation of otherwise silent brain lesions, emerging as more sensitive indicators of cerebral involvement than neurological symptoms and signs.

The MRI findings mirror clinical findings to the extent that evolution of T2-hyperintense lesions correlates with cognitive decline over a decade or more (Rudick *et al.* 2006b) and grey matter volume loss differentiates those with cognitive impairment from those without (Benedict & Bobholz 2007; Ghaffar & Feinstein 2007). However, there are discrepancies between findings from MRI and from neuropsychology and increasingly studies are turning to functional imaging approaches to explore a putative 'functional reserve' that might explain interindividual variation in cognitive loss (Ghaffar & Feinstein 2007).

Presentation with dementia is occasionally encountered and can raise important problems of differential diagnosis. Koenig (1968) described seven patients in whom dementia was the sole or predominant manifestation of the disease, the MS being of a relatively silent variety neurologically. The onset was usually fairly acute with memory loss, confusion, disorientation or personality change. Some showed slight fluctuations in the level of mental functioning from day to day. Three showed progressive deterioration and only one had a partial remission. Neurological symptoms of brainstem or cord dysfunction had preceded the dementia or accompanied its onset in four cases, but all showed evidence of disseminated CNS disease on careful examination. Koenig suggested that 'silent' or unrecognised MS may be a commoner cause of dementia than is generally recognised. Young *et al.* (1976) reported further examples with intellectual impairment as the presenting symptom or forming a prominent part of the picture from the earliest stages.

Hotopf *et al.* (1994) describe two particularly instructive patients in whom the cognitive changes were at first attributed to psychiatric illness.

A 41-year-old man had a 2-year history of change of personality, becoming quiet, vague and forgetful. He was involved in a series of road traffic accidents and had begun to sleep for long periods. His attitude to his problems was one of bland indifference. There was no family or personal history of psychiatric illness.

On examination he was alert but his affect was strangely inappropriate. He was intermittently disorientated in time

and place and there were tendencies to confabulate and perseverate. Concentration, attention and memory were poor, and he had difficulty with verbal fluency and sequential tasks. He made occasional naming errors and paraphasic mistakes when writing. On first contact with the neurological services his mental state had seemed sufficiently bizarre to raise a diagnosis of hysteria, reinforced by his striking lack of concern about his poor performance on tests of cognition.

The only physical signs were an extensor plantar response, which was not present on re-examination, and lack of left arm swinging while walking. Two months later he showed a plantar grasp reflex and a positive glabellar tap. Psychometric testing revealed a verbal IQ of 73 and performance IQ of 63, consistent with moderate to severe decline of intellect. CSF examination showed a raised protein with oligoclonal bands and visual-evoked responses were abnormal. MRI showed periventricular abnormalities and widespread changes in the hemispheres consistent with MS. Screening tests for other causes of dementia were negative. Over the next 8 years he showed steady deterioration to severe global cognitive deficit, with dysphasia, severe ataxia and incontinence of urine.

The second patient presented at the age of 35 with a 3-year history of difficulties with concentration and memory. He had become increasingly withdrawn but showed no concern over his symptoms. When first seen in a neurological clinic a non-organic psychiatric illness was suspected. He had diabetes, and for 6 months there had been an insidious loss of vision. Neurological findings included bilateral optic atrophy and later some evidence of gait disturbance, but there were no other neurological abnormalities. Cognitive examination subsequently showed disorientation, impaired concentration, poor memory, dyscalculia and reduced verbal fluency. Psychometric testing confirmed these deficits and showed a verbal IQ of 73. CSF examination showed oligoclonal bands in the presence of normal total protein, and visual-evoked responses were abnormal. MRI revealed changes consistent with multiple sclerosis (Fig. 14.1). Over the next 18 months he continued to show gradual cognitive decline without any marked physical symptoms or signs.

Sometimes the rate of progression of dementia is astonishingly rapid, as in the patient described by Bergin (1957).

A woman of 30 developed brief retrobulbar neuritis followed 1 year later by diplopia, ataxia and precipitate micturition. Over 3 months she became severely incapacitated, apathetic, retarded and vague. Examination showed a pale left optic disc, fine lateral nystagmus, slight right facial and arm weakness, incoordination of the legs and upgoing plantar responses. The CSF showed 18 lymphocytes/mL and a paretic Lange curve. One week after admission she became confused, uncooperative and disorientated, doubly incontinent and with gross evidence of intellectual impairment. Two weeks later she could not understand even simple sentences. Electroencephalography (EEG) showed random irregular slow waves in all areas and the air encephalogram showed moderate ventricular enlargement. Six weeks after admission she was bedfast, making noises but no recognisable words. The only active limb was her left arm, which was used to strike out at people and tug at her hair. Within 10 weeks she died and post-mortem examination showed well-defined plaques throughout the brain, cerebellum, brainstem and cord.

Abnormalities of mood

Studies from patients in the community or in the clinic show lifetime rates of major depression of up to 50% (Ghaffar & Feinstein 2007). The symptoms are essentially the same as for primary major depressive disorder, although some evidence suggests that irritability is more common than feelings of low esteem. There has been much debate as to the origins of depression in MS. Psychosocial variables are undoubtedly important and increasing attention has turned to psychosocial interventions designed to increase quality of life and reduce mood disturbance with some evidence for efficacy (Malcomson *et al.* 2007). However, there is also evidence from neuroimaging for biological effects of the disease on mood, with some evidence pointing towards left medial inferior prefrontal cortical lesions and dominant anterior temporal atrophy being associated with depression (Feinstein *et al.* 2004). In truth, for most patients it will be a combination of personal circumstances, premorbid predisposing factors and biological effects of disease that give rise to depressive events. Irrespective of its derivation, the degree of depression in MS can be severe, and suicide has been reported in a considerable number of cases.

A variety of other affective changes are common in MS. Euphoria, a bland elevation of mood out of keeping with the patient's physical condition, was once thought to be the usual picture, but it is now clear that depression is at least as

common. Much probably depends on the stage at which the patient is examined and whether some degree of intellectual deterioration has occurred. The transition over time from depression to euphoria can sometimes be observed in the individual patient. Frank bipolar affective disorder is twice as common in MS as in the general population (Ghaffar & Feinstein 2007).

Euphoria was defined by Surridge (1969) as a mood of cheerful complacency out of context with the patient's total situation. It differed from the elation of hypomania in not being accompanied by motor restlessness, increased energy or speeding up of thought processes. All but two of the euphoric patients in his series showed intellectual deterioration, and the group as a whole was significantly more disabled than the depressed or normal groups. The phenomenon is possibly related not only to changes of mood but also to denial or impaired awareness of disability. Quite often, however, the initial impression of euphoria proves to be misleading, and the evidence of cheerfulness or complacency subsides as the interview progresses. Indeed Surridge found that 8 of 28 euphoric patients confessed to feeling miserable and depressed despite the strong outward impression that they were unreasonably cheerful. No doubt an element of emotional lability is often associated with euphoria and adds to the difficulty of assessing the patient's true subjective feelings.

Disorders of emotional control include true exaggeration of emotional feeling (lability of affect) or exaggeration of expression that is unbacked by an equivalent degree of feeling (disorder of affective expression). The latter may indeed be incongruous with the underlying mood and is essentially similar to the disorder of emotional expression seen in pseudobulbar palsy. This affective state has been termed 'involuntary emotional expression disorder' (Cummings *et al.* 2006) and affects up to 10% of people with MS. Antidepressants, levodopa and a dextromethorphan/quinidine combination have all been suggested as possible treatment strategies (Ghaffar & Feinstein 2007).

Psychoses

Psychotic illnesses have been described in the disease, sometimes late in the course but occasionally as a presenting feature. A relatively recent database study suggested rates in MS of more than twice that in the general population (Patten *et al.* 2005). This finding substantiates previous small series or case reports of the co-occurrence of MS and psychosis. With regard to schizophrenia, Davison and Bagley (1969) identified 39 acceptable cases in the literature, 27 with paranoid-hallucinatory and 12 with hebephrenic-catatonic illnesses. The symptomatology did not differ appreciably from that of other schizophrenic psychoses, except that expansive delusional states seemed to be particularly common, and neurological symptoms such as paraesthesiae were some-

times incorporated into paranoid–delusional systems. The psychoses often developed early in the disease, tending to cluster around the time of first appearance of neurological abnormalities.

Feinstein *et al.* (1992b) report an attempt to explore the possible contribution of brain pathology to psychotic illness by comparing groups of 10 patients with and without psychosis. These were well matched for age, disability, duration of disease and disease course. The psychoses were equally divided into two broad categories of schizophrenia and affective psychosis. In all cases the neurological disorder had preceded the onset of psychosis, the mean interval being 8.5 years. On MRI there was a trend for the psychotic group to have a higher total lesion score, particularly in the periventricular regions and in the areas surrounding the temporal horns bilaterally. This reached statistical significance when the left temporal horn and adjacent left trigone areas were combined. Such findings point to a possible aetiological role of brain pathology in contributing to psychotic developments. No differences could be determined in this respect between the schizophrenic and affective psychotic groups.

Presentation with psychosis is rare, but sometimes the neurological abnormalities are so overshadowed by the mental picture that the true diagnosis is missed. Such cases are obviously important. Parker (1956) reported a patient who became apathetic and withdrawn in his early twenties and was diagnosed as suffering from schizophrenia. He showed slight hesitancy of speech and irregular nystagmus but this was ignored at the time. Attempts at treatment and rehabilitation met with no success. A few years later he was fatuous and childish, and by then showed impairment of memory, gross spasticity and pronounced incoordination. He died suddenly and the pathological changes of MS were revealed.

Geocaris (1957) reported four instructive examples of patients admitted with an initial diagnosis of psychosis, three with schizophrenia and one with severe depression, who showed evidence of MS a few weeks or months later. Mur *et al.* (1966) reported three unusual examples in patients over 50 in whom psychotic features dominated the course. One had a paranoid psychosis for 5 years before neurological symptoms appeared in the form of a spastic paresis with dementia; another had a relapsing paranoid syndrome for 11 years accompanied by ataxia of gait and intellectual impairment; and the third had a temporary gait and speech disturbance at the onset of a depressive syndrome that dominated the picture until death. In all three cases the plaques were found to be predominantly in the cerebral hemispheres.

Finally, two patients reported by Matthews (1979) are important in drawing attention to the possibility that acute mental disturbance, remitting completely, may sometimes be the initial manifestation of the disease.

In the first patient, a girl of 19, the presentation was with intermittent confusion and episodes of markedly bizarre behaviour, leading to a diagnosis of probable schizophrenia. No neurological abnormalities were apparent on examination. Epileptic fits developed during a course of electroconvulsive therapy, leading to lumbar puncture which revealed mild pleocytosis in the CSF. EEG was diffusely abnormal, and she was treated with phenytoin. Over the course of the next few weeks she recovered completely, EEG also reverting towards normality. Thereafter she remained well for 3 years. Symptoms typical of MS then made an appearance, the disease following a relapsing and remitting course over the next few years.

The second patient developed depression of acute onset at the age of 24. She became increasingly withdrawn, self-neglectful and intermittently incontinent of urine and faeces. The tendon reflexes were noted to be increased in the lower limbs and the plantar responses were extensor. Examination of the CSF showed abnormalities compatible with MS and EEG showed a marked excess of slow activity bilaterally. Her mental state varied greatly. At times she was almost normally communicative; at others she gave bizarre replies to questions and had outbursts of shouting and kicking. Treatment with prednisolone led to gradual neurological and mental improvement, the patient becoming entirely normal some 3 months from the onset. Several months after recovery she developed unilateral optic neuritis and bilateral abnormalities of visual-evoked responses, clearly indicative of MS.

The question of possible presentations with psychiatric disorder is clearly of great interest, not least in pointing to the need for neurological examination and comprehensive review of the past medical history in psychiatric patients. Particular interest would attach to presentations without organic features in the mental state. In a careful review of 91 patients with MS from a defined region of New Zealand, Skegg (1993) found that 19 had been referred to psychiatrists before the disease was diagnosed, often with non-organic symptomatology. However, only in two cases did a link between such symptoms and developing MS seem plausible. Skegg's review highlights the difficulty of reaching firm conclusions on the issue.

Influence of emotions on the disease

Physical and emotional traumas have often been regarded as precipitants of MS, or as provocative factors that help to determine relapses. Pratt (1951) attempted to examine the situation in detail and found that 38% of MS patients had suffered some emotional stress in the months antedating the

onset, compared with 26% of controls suffering from other nervous system disease. The difference fell just short of statistical significance, but in most cases the stresses had not been unduly severe. With regard to later relapses, 25% were preceded by emotional stress, a figure virtually identical with the proportion of controls who had stress antedating their illness. Thus in the group as a whole there was no clear evidence to incriminate emotional factors in causing relapses.

In individual cases, however, a suggestive relationship was sometimes observed. In one patient a relapse occurred within an hour of receiving bad news by letter. In another numbness developed in the legs immediately after a narrow escape from a motor cycle accident, and in another the right arm became useless the morning after breaking off an engagement. Short of major relapses, some patients found that emotional disturbances led to transient exacerbation of the symptoms of a pre-existing lesion. This was significantly commoner than among the controls, and the examples were often clear-cut and impressive, usually occurring within minutes of the emotional upheaval. In different patients, for example, worry led invariably to increased unsteadiness, anger to weakness of a leg, fear or quarrelling to weakness of the legs lasting several hours, self-consciousness to blurring of vision or exacerbation of diplopia.

There is some evidence from animal models of MS that stress might exacerbate the biological process, perhaps by disturbing the hypothalamic-pituitary axis (Bomholt *et al.* 2004; Gold *et al.* 2005; Heesen *et al.* 2007). In addition, recent clinical studies and a meta-analysis have further supported the role of stress (Mohr *et al.* 2004; Mohr & Pelletier 2006). These findings emphasise that ongoing social and psychological support will have an especially important part to play in the management of patients, and may sometimes serve to avert or delay relapses.

Schilder's disease (diffuse cerebral sclerosis, encephalitis periaxialis diffusa, myelinoclastic diffuse sclerosis)

The generic term 'diffuse cerebral sclerosis' has been applied to a variety of conditions in which widespread demyelination and gliosis occur in the white matter of the hemispheres. Histological examination allows a more precise classification, and it seems that reported cases have included examples of familial leucodystrophy and subacute sclerosing leucoencephalitis in addition to cases pathologically related to MS (Greenfield & Norman 1963). Greenfield and Norman suggest that the latter is the most appropriate restricted use for the term 'Schilder's disease'. Nevertheless, some believe that it represents no more than an exceptionally severe variety of MS occurring in early life (Compston 1993). In any case it is rare and most of the evidence comes from case reports (Kotil *et al.* 2002).

Most cases have been reported in children but adults may also be affected (Garell *et al.* 1998). Both sporadic and familial examples are encountered. The varied neurological manifestations include spastic paraparesis, sensory changes and often progressive cerebral blindness. Central deafness may also occur. Mental functions are affected early and severely, dullness and apathy progressing to dementia and stupor. Acute and widespread demyelination may cause cerebral oedema, raised intracranial pressure and papilloedema (Compston 1993). The disease usually runs a rapid course, with death within a few months though some patients survive for 2 or 3 years. Temporary remissions have been described, and very occasionally recovery (Ellison & Barron 1979). A good response to corticosteroids has been reported (Kurul *et al.* 2003). The CSF shows changes resembling those of MS. Brain imaging usually shows a characteristic picture, with symmetrical, sharply defined, low-density lesions in the occipital or frontal regions.

Pathologically, the brain shows large areas of brownish or greyish softening in the white matter, usually maximally involving the occipital lobes and spreading forwards through the hemispheres symmetrically (Greenfield & Norman 1963). Microscopically, they show complete demyelination, and in the older lesions axonal destruction as well. In the smaller lesions the picture is indistinguishable from that of MS.

Psychiatric aspects

A point of psychiatric interest has been the occurrence of pictures indistinguishable from schizophrenia in patients who have later shown Schilder's disease at post-mortem. Several such reports have now accumulated, mostly in patients who had displayed little or nothing by way of neurological disturbance during life. The cerebral pathological findings were in consequence usually unexpected.

Ferraro (1934, 1943) reported two examples in adolescent boys who had been clinically diagnosed as suffering from hebephrenic schizophrenia. In the first, the disorder progressed over 2 or 3 years without neurological abnormalities or features indicative of an organic psychosis at any stage. The second showed fleeting and inconstant neurological abnormalities early in the illness, and obvious intellectual deterioration during the months immediately preceding death 3.5 years later.

Holt and Tedeschi's (1943) patient showed a classic catatonic picture and died within a week. There were no abnormal neurological signs. He had suffered a previous episode of acute catatonic schizophrenia 18 years previously. Roizin *et al.*'s (1945) patient similarly showed a picture of catatonic schizophrenia, with auditory hallucinations and periods of stupor alternating with outbursts of impulsive destructive behaviour. Again, there were no neurological abnormalities and the patient died within a few weeks. Jankowski (1963)

described a chronic example in a man of 28 with repeated hospitalisations over 4 years prior to death. Severe affective changes of hebephrenic type developed gradually and without discernible intellectual deterioration. Late in the illness the pupillary reactions to light were lost and he complained of impaired vision, but the CSF remained normal.

Ramani (1981) has reported yet another example, this time diagnosed by computed tomography (CT) during life and subsequently confirmed by biopsy.

A man of 34 had suffered from chronic schizophrenia, refractory to treatment, for 5 years. It had started with mood swings, leading on to progressive withdrawal, disorganisation of thinking, and paranoid delusions and hallucinations. He showed bizarre posturing at times and echolalia. There was no family history of schizophrenia. On examination the only neurological abnormalities were bilateral extensor plantar responses and a suggestion of a snout reflex. CT showed large, symmetrically situated, low-density areas in the frontal regions.

In most of these examples the accent of the pathological process was on the frontal lobes of the brain, in contrast to the usual predominant involvement of the occipital lobes. This may have accounted for the atypical presentation and development of the disease.

Tuberous sclerosis (tuberose sclerosis, epiloia)

Tuberous sclerosis complex (TSC) is a multisystem disorder most commonly affecting brain, skin, kidneys and heart. It occurs with a birth incidence of 1 in 6000 to 1 in 10000 (Wiederholt *et al.* 1985; Osborne *et al.* 1991) and as might be expected from the systems affected has a complex clinical appearance (Crino *et al.* 2006; Rosser *et al.* 2006). Skin defects include fibromas and hypomelanotic macules seen typically as leaf-shaped dull white patches, particularly over the trunk and buttocks; renal manifestations include cysts and angiomyolipidomas; and cardiac features include rhabdomyomas causing dysrhythmias. However, neurological symptoms are the most common and result in the most impairment. The first clinical manifestations are usually in infancy or childhood although presentation in adulthood can occur, sometimes on account of late-onset epilepsy or sometimes when characteristic skin lesions or neuroimaging signs are discovered. The disorder results from mutations in two genes, *TSC1* (chromosome 9q34) and *TSC2* (16p13.3), which occur spontaneously in approximately two-thirds of cases and are inherited in an autosomal dominant fashion in the remainder (Webb & Osborne 1992).

Neuropsychiatric symptoms

Seizures occur in over 90% of cases at presentation (Rosser *et al.* 2006). All forms of epilepsy, with the probable exception of classic absence seizures, are reported although partial motor and complex partial seizures occur most often. In severe cases the presentation is frequently with infantile spasms. EEG is usually abnormal in patients with severe disease or currently active epilepsy, but can be quite normal in others. No specific pattern is diagnostic. Medical management is the same as for other epilepsies, although severe treatment-resistant seizures are common. Vigabatrin appears to be particularly effective for infantile spasms (Rosser *et al.* 2006) and surgical resection of isolated tubers resulting in epileptic foci can be useful.

Cognitive impairment is common, often profound, but not invariable. In a large study from the UK, the distribution of cognitive ability in TSC was shown to be bimodal as half of the population had a normal IQ and one-third an IQ in the profoundly affected range (Joinson *et al.* 2003). Moderate to severe mental retardation is more common in those with infantile spasms and both epilepsy and cognitive impairment tends to be more severe in those with *TSC2* mutations.

Autistic spectrum disorder is also common in TSC, although prevalence rates vary hugely in different studies probably because of different assessment measures (Rosser *et al.* 2006). Reported rates of autism in TSC range up to 60% but it should be noted that less than 4% of all autism is attributable to TSC.

Psychotic symptoms can occur. Thus Critchley and Earl (1932), reporting institutionalised patients, described the essential psychological feature as a combination of intellectual defect with a 'primitive form of catatonic schizophrenia'. It is now clear that psychotic developments, like the learning disability, are by no means as invariable as these writers believed. Nevertheless, the following case reported by Zlotlow and Kleiner (1965) illustrates the type of schizophrenia-like picture that may be encountered.

The patient had fits from the age of 4 to 7 years but thereafter excelled at school. Pimples developed on the nose and cheeks from 15 onwards. In adolescence he became shy, solitary and withdrawn, and at 20 a severe mental change occurred: he became nervous and easily upset, with frequent tantrums and childish unreasonable behaviour. Seizures became frequent and he appeared slightly dull mentally. Adenoma sebaceum was by this time well developed, EEG showed abnormalities over the left hemisphere and the air encephalogram showed slight ventricular dilatation.

The mental condition worsened, with fear of leaving the house, feelings that he was losing control of his limbs, and

beliefs that people were laughing and talking about him. In hospital at 23 he was retarded, emotionally dull and spoke slowly in whispers. He denied auditory hallucinations but saw 'moving pictures' before his eyes. The IQ was low (70) with evidence of deterioration. He remained seclusive and withdrawn, with frequent mood swings, irritability and overactivity.

At 34 he was regarded as a chronic schizophrenic, often incontinent, speaking incoherently and with long episodes of mutism. Periods of irritable excitement alternated with catatonic stupor. He remained essentially unchanged over the following years. Skull radiography now showed small calcifications in the pineal region and a number of globular vacuoles in the frontal and temporal bones. EEG showed much disorganised slow activity. He was untestable psychometrically.

Magnetic resonance imaging is used to diagnose TSC and to estimate the extent and document the site of lesions in the brain (Luat *et al.* 2007). Cortical tubers are shown as well-circumscribed lesions on T1-weighted images and as hyperintensities on T2-weighted sequences. FLAIR and MTI can both add to the sensitivity in detecting cortical tubers. MRS shows decreased *N*-acetylaspartate indicative of neuronal loss. Increasingly, DTI has been used to document tract damage in TSC and may be clinically useful in identifying epileptogenic foci in some studies in combination with various positron emission tomography (PET) imaging techniques (Luat *et al.* 2007).

Pathology

The striking pathological change in the brain consists of pearly white nodules 0.5–3 cm in diameter, situated along the ventricular surfaces and sometimes over the cortical surface as well. The nodules are hard, like rubber or potato (hence 'tuberous'), and may contain minute calcareous fragments. Histologically, they contain dense glial material and curious large cells which are thought to derive from undifferentiated spongioblasts. Frank neoplastic changes may be apparent in the form of glioblastoma multiforme or spongioblastoma. Short of this, the nodular protrusions are occasionally sufficiently large to obstruct the flow of CSF within the ventricles. The intervening brain tissue is often markedly disorganised, with abnormal cytoarchitecture, reduction of neurones and increased gliosis. The cerebellum and cord may be similarly affected.

These changes result from mutations in *TSC1* and *TSC2*, which encode the proteins hamartin and tuberlin, respectively. A very large number of mutations in both are noted, many confined to a family or arising spontaneously in an

individual. Together these genes account for most of the cases, although there may yet be other *TSC* genes. In a series of over 300 families and patients, approximately one-third had no apparent *TSC1* or *TSC2* mutation (Au *et al.* 2007). The gene products, hamartin and tuberlin, interact with each other through coiled-coil domains (van Slegtenhorst *et al.* 1998) and the heterodimer contributes to intracellular signalling in a number of critical pathways. Upstream of *TSC1/TSC2*, these include the mitogen-activated protein kinase, phosphatidylinositol 3-kinase and glycogen synthase kinase-3 pathways. These pathways have been widely implicated in other brain diseases including schizophrenia and Alzheimer's disease (Lovestone *et al.* 2007; Hooper *et al.* 2008) as well as in normal neurodevelopmental processes (Logan & Nusse 2004; Davila *et al.* 2007). Downstream of *TSC1/TSC2*, signalling through mTOR (mammalian target of rapamycin) controls, among other effects, cell growth and differentiation. The mTOR pathway has been clearly shown to be critical to neurodevelopment and to the functioning of the adult nervous system (Swiech *et al.* 2008). It is clear then that the *TSC1/TSC2* genes are at the centre of a network of signalling processes which independently have been shown to be essential to both normal neuronal development and to normal mature neuronal function and are altered in other degenerative and developmental brain diseases. De Vries and Howe (2007) propose that the complex functions as a global regulator and integrator of a range of physiological processes and that the clinical features of the disease can result from disruption of these processes and that tubers and seizures are neither a necessary nor sufficient explanation of the neurocognitive phenotype.

Neurofibromatosis

The neurofibromatoses comprise a number of related conditions characterised by skin pigmentation and tumour formation at a number of sites. Most features arise in tissues of neural crest origin and Schwann cells are the principal components in tumour formation. By far the most common form is von Recklinghausen's disease, now called neurofibromatosis (NF)1, with the characteristic development of peripheral neurofibromas. Prevalence is estimated to be 0.0003 (Littler & Morton 1990). The related disease NF2 can lack distinctive skin manifestations and typically presents with bilateral acoustic neuromas (schwannomas). All other variants are considerably rarer.

Both NF1 and NF2 are inherited as autosomal dominant disorders, although in a very high proportion these represent new mutations. The rate of new mutations of NF1 (1×10^{-4} per gamete per generation) is the highest rate of new mutation in any known human gene and causes half of all cases. Mutations seem to occur most often in paternally inherited chromosomes, suggesting an effect of imprinting (Stephens *et al.* 1992). The *NF1* locus on chromosome 17

encodes the protein neurofibromin (Trovo-Marqui & Tajara 2006). In fact the genetics are complex in a very small minority of cases with mutations in two genes involved in DNA repair (*MLH1* and *MSH2*) that result in somatic mutations in neurofibromin but not germline mutations (Wang *et al.* 2003). The disorder in this case is also called brain tumour-polyposis syndrome 1 or Turcot syndrome. Furthermore, a significant proportion, perhaps as high as 20%, of patients, have deletion of a region containing the *NF1* gene and this causes a more severe form of the disease that includes mental retardation in particular (Dorschner *et al.* 2000; Venturin *et al.* 2004). The neurofibromin protein has complex roles in neurones including regulating the activity of some key protein kinases, modifying microtubule assembly and altering CREB function. All three processes have been implicated in cognitive processes and microtubule function has been shown to be altered in other brain diseases, most notably Alzheimer's disease and some variants of motor neurone disease. The interactions between neurofibromin and the signalling cascades and microtubule function has been reviewed by Weeber and Sweatt (2002).

The *NF2* gene on chromosome 22 encodes the protein neurofibromin-2, also called merlin because it was moesin-, ezrin- and radixin-like. The function of the protein product is not fully understood but it may have tumour-suppressor properties. Most mutations result in a truncation of the gene and result from frameshift or nonsense mutations or splice variants. Genotype–phenotype correlations suggest that splice variants result in markedly different forms of the disorder (Parry *et al.* 1994, 1996).

Clinical manifestations of NF1

The major defining features of von Recklinghausen's disease consist of café-au-lait spots, peripheral neurofibromas and Lish nodules. However, much of the morbidity and mortality in the condition are dictated by additional complications involving many body systems. Diagnostic criteria have been proposed by the National Institutes of Health and can be of particular importance in genetic counselling (NIH Consensus Development Conference 1988).

The café-au-lait spots are brown macules of varying size that appear during childhood, most affected persons having at least six. Those over 0.5 cm in diameter in children and 1.5 cm diameter in adults are of significance. They may be accompanied by freckling in the axillary or inguinal regions. The peripheral neurofibromas usually develop around the time of puberty and gradually increase in size and number with age. They are largely composed of Schwann cells together with perineural fibroblasts and smaller numbers of other cells. Dermal neurofibromas, derived from terminal nerve branches in the skin, appear mainly on the trunk as soft discrete nodules varying in diameter from 1 mm to several centimetres. Nodular neurofibromas are situated on periph-

eral nerve trunks and have a firmer consistency. Lish nodules are pigmented hamartomas of the iris, best seen on slit-lamp examination.

Other features of less diagnostic significance include macrocephaly in almost half of patients, and short stature in perhaps one-third (Huson 1994). Campbell de Morgan spots consist of tiny cherry-red skin angiomas. Slight clumsiness and certain aspects of facial appearance also seem to be characteristic. Riccardi (1981) reported that 30–40% of patients showed speech impediments by way of hypernasality, slowing or imprecise pronunciation. Headaches of various types are common.

Several of the complications that develop involve the nervous system. Plexiform neurofibromas consist of large subcutaneous swellings with ill-defined margins, sometimes causing enlargement of part of the face or a limb and often producing marked cosmetic deformity. Those involving peripheral nerve trunks can be painful. They occasionally undergo malignant change to neurofibrosarcoma. Other complications include spinal root and cranial nerve neurofibromas, malignant change in peripheral nerve neurofibromas, and gliomas particularly of the optic nerve and chiasm. Up to one-fifth of children with the disorder develop astrocytomas, often in the optic system resulting in loss of vision (Listernick *et al.* 1994). Aqueduct stenosis may lead to hydrocephalus, and there is a small increased risk of epilepsy. Meningiomas are uncommon except in NF2.

Tumours affecting other parts of the body include rhabdomyosarcoma, phaeochromocytoma and carcinoid tumours of the duodenum. Neurofibromas may be found in the viscera, mediastinum, oral cavity or larynx, sometimes with serious consequences. Skeletal abnormalities include scoliosis, vertebral scalloping, and pseudoarthrosis of the distal long bones. Some 6% of patients develop hypertension.

The clinical course is variable: café-au-lait spots are often recognised in the first year of life, optic gliomas in children between the ages of 3 and 5 years and neurofibromas in adolescence (Zaroff & Isaacs 2005). Prognosis is good even if gliomas develop as they progress slowly and survival rates are greater than 80% at 10 years after onset (Guillamo *et al.* 2003).

Neuropathology

In addition to the pathologies described above, the brain may show subtle abnormalities on detailed examination that reflect cortical dysgenesis (Wiestler & Radner 1994). Disturbances of cytoarchitecture are common, with random orientation of neurones and disarray of cortical lamination. Neuronal heterotopias in the subcortical white matter appear to result from disturbed cell migration during embryogenesis. Gyral abnormalities may be seen such as pachygyria or polymicrogyria.

Focal subependymal glial proliferations may project into the ventricular system or contribute to aqueduct stenosis. Areas of fibrillary gliosis have been described in the cerebellum and adjacent leptomeninges, also scattered micronodular vascular proliferations. Neuropathological features of this nature could be relevant to the mental retardation encountered in a proportion of subjects (see below).

Psychiatric aspects

Intellectual impairment has long been recognised in a proportion of subjects with von Recklinghausen's disease, although severe degrees of handicap are rare. Ferner (1994) concludes that the majority of individuals with NF1 have IQs in the low average range, with about 8–10% scoring below 70. However, some can show superior academic ability. Performance IQs tend to be considerably lower than verbal IQs, and specific learning difficulties appear to be common.

Children with NF1 often show underachievement at school. Language development is sometimes delayed and a high proportion have difficulties with reading and writing. In Huson *et al.*'s (1988) survey in south-east Wales, 10% of 124 patients had attended special schools and a further 17% had required remedial class teaching. Neuropsychological evaluation has shown special problems with language, visuospatial tasks, memory and sustained attention, also difficulties with organisation and planning. Impairments are common with both gross and fine motor coordination in the absence of detectable neurological lesions.

Behavioural disorder has also been stressed in childhood, with hyperactivity and impulsive and aggressive tendencies. Attention deficit hyperactivity disorder type symptoms are present in about one-third of patients (Kayl & Moore 2000). Other problems reported in children include a higher rate of anxiety and depression, social problems and aggression (Johnson *et al.* 1999).

In Rosman and Pearce's (1967) post-mortem study, abnormalities of cerebral architecture and white matter heterotopias were prominent in all patients with intellectual impairment, with less marked changes in those of normal intelligence. However, MRI studies have shown little relationship between intellectual ability and such features as high-intensity lesions on T2-weighted images, suggesting that the cerebral basis of impairment is too subtle to be detected by this means (Ferner 1994).

Other psychiatric disorders have received little attention in neurofibromatosis despite the psychological burden which many subjects must bear. The disfigurement occasioned by the disease can be a grave social handicap, especially when the face is involved. Puzzled or hostile reactions from others are frequently encountered and social ostracism occasionally results. Despite this the majority of patients seem to be reasonably well adjusted and severe psychiatric disturbance appears to be rare. Samuelsson

(1981) reviewed the earlier literature which stressed apathy and depression, also personality disturbance and psychotic states, but these were often in specially selected patients. Samuelsson's own survey involved a thorough psychiatric examination of the 74 cases known to the health services in Gothenburg. Almost one-third were considered to suffer from mental illness in some degree, and 13 had had treatment in psychiatric hospitals. The most common diagnoses were of depression, alcoholism and anxiety. One patient showed social phobia. The patients with mental illness were more often mentally retarded than those without, and showed a significantly increased frequency of neurological abnormalities reflecting CNS involvement. The condition had sometimes had a considerable impact on the patients' lives, including avoidance of sports and other exposures in public, sensitivity about remarks from others, or fear of the nodules becoming malignant. Several patients had decided against procreation.

Samuelsson's study was uncontrolled. Hughes (1994) and Ferner (1994) report an unpublished survey of 103 patients with NF1 which showed that diagnosed psychiatric illness was no more common than in controls matched for age and sex. Moreover, there was no significant increase in anxiety and depression as measured by the Spielberger Anxiety Trait Inventory for Children or the Hospital Anxiety and Depression Scale. One-third of the patients had experienced hostile reactions from strangers because of unsightly neurofibromas. The rates of marriage were similar to those of the control group despite such cosmetic problems.

Riccardi (1981) suggests that the psychological burdens experienced in the disease are among the most important elements for patient care. In particular he stresses that frank discussion of the various features and complications serves to decrease adverse concerns, and provides a realistic context for making future decisions.

Friedreich's ataxia

Friedreich's ataxia is the commonest of the spinocerebellar ataxias and one of the commonest of the hereditary diseases of the nervous system, occurring in approximately 1 in 50 000 white Europeans (Delatycki *et al.* 2000). However, there are variances in this frequency: relatively higher rates have been reported in French Canadians (Barbeau *et al.* 1984) and in southern Italy (Romeo *et al.* 1983) probably due to consanguinity, while relatively lower rates are reported in Finland (Juvonen *et al.* 2002). Clinically, it occurs both sporadically and familiarly with the pedigrees often having the appearance of autosomal recessive inheritance. However, Friedreich's ataxia is both heterogeneous and, in its main form, a non-mendelian disorder and these combine to give the mixed pedigrees seen in clinical series. The primary locus for the disease (*FRDA1*) is on chromosome 9q in the gene encoding frataxin (FXN). The mutation has been shown

to be an expansion in a GAA trinucleotide repeat in exon 1, the normal range of this repeat series being 5–30 and with disease being caused by more than 70 and up to 1000 repeats (Gatchel & Zoghbi 2005; Wells 2008). A second locus for the disease (*FRDA2*) exists in some families on chromosome 9p (Kostrzewa *et al.* 1997).

Clinical features

The onset is typically in the first or second decades of life. Unsteadiness of gait may at first be mistaken for the clumsiness of adolescence. With progression the gait becomes broad-based and lurching, action tremor appears in the arms and titubation may develop in the head. The trunk may eventually be implicated rendering even sitting difficult. Nystagmus is present in one-fifth of cases, and the speech is dysarthric. Cerebellar dysfunction shows also in generalised hypotonia and asynergia of movement. Weakness and wasting sometimes develop distally in the limbs and the tendon reflexes are eventually lost. However, the plantar responses are upgoing, indicating pyramidal tract involvement. Sphincter control is usually unaffected until late in the disease. Posterior column changes are manifest in defective vibration and position sense, although other sensory modalities are usually intact. Rombergism is detectable early on. Characteristic deformities with kyphoscoliosis or pes cavus are found in almost all cases, the latter sometimes long antedating other manifestations. Optic atrophy occurs in about one-quarter of cases and sensorineural deafness in 10%. Myocardial involvement is common and diabetes is prone to develop (Harding 1983; Albin 2003; Bhidayasiri *et al.* 2005).

The disease pursues a slowly progressive course though in occasional cases long stationary periods are encountered. Incomplete and abortive cases also occur in which the condition is static or progresses very slowly indeed. In the typical case severe incapacity with inability to walk is reached within 15 years of onset. Few patients live more than 20 years after the disease is declared, although survival into the sixth or seventh decades is not unknown.

Pathology

The brunt of the pathology falls on the long ascending and descending tracts of the cord. Degeneration is most marked in the posterior columns, spinocerebellar tracts and pyramidal tracts. Fibrous gliosis replaces the atrophied fibres. Atrophy may also be seen in the dorsal roots of the cord and the tracts and nuclei of the lower brainstem. The peripheral nerves show loss of large myelinated fibres and segmental demyelination. Purkinje cell loss has been reported in the cerebellum, also atrophy of the dentate nuclei and superior cerebellar peduncles. It can be hard to distinguish primary degenerative changes from those secondary to circulatory

disturbances arising from the patient's cardiac disease. The myocardium may show hypertrophy of muscle fibres and fibrosis.

The primary genetic defect in Friedreich's ataxia is in the gene encoding frataxin, a mitochondrial protein (Schapira 2006; Wells 2008). As pointed out by Wells (2008), since this discovery Friedreich's ataxia has become one of the most studied neurological disorders at the pathophysiological and molecular level. This work is bearing fruit: the triplet repeat in the gene has been convincingly shown to reduce transcription as it induces the formation of 'sticky' DNA, i.e. the physical association of purine–purine–pyrimidine triplexes in negatively supercoiled plasmids. The relative loss of frataxin results in an imbalance in sulfur–iron metabolism and subsequent hypersensitivity to oxidative stress. This in turn has led to some very clear potential therapeutic strategies which are being intensively investigated (Schols *et al.* 2004; Pandolfo 2008).

Psychiatric aspects

Psychiatric interest in the disorder has centred chiefly on the intellectual impairment noted in some patients (reviewed in Corben *et al.* 2006), and on the severe mental disturbances that occasionally arise.

Intellectual impairment has been reported in some series of patients but not in others. Friedreich himself noted an absence of mental defect in his cases, but later workers suggested that a considerable proportion showed mental deterioration, possibly associated with extension of the pathological process to the cerebral cortex. Bell and Carmichael (1939) reviewed 242 families from the literature and noted that mental impairment had been present in almost one-quarter. This varied in degree, the grade of defect tending to be similar in different affected members of a given family. Severe effects on cognition appeared mainly to be confined to family members afflicted with the neurological disorder, and had usually been conspicuous from the early stages.

More recent studies have shown verbal and visuospatial deficits correlating with cerebellar atrophy (Wollmann *et al.* 2002), slowed reaction times (Hart *et al.* 1986; White *et al.* 2000), and results on neuropsychological testing reminiscent of mild frontal lobe disease (Botez-Marquard & Botez 1993).

Psychotic developments have also been recognised in patients with Friedreich's ataxia. Many different forms of abnormal mental state are described, but mostly in isolated cases so that the overall incidence is hard to assess. The form that has attracted most attention is a schizophrenia-like illness characterised by paranoid delusions and outbursts of excitement. Davies (1949) described a patient who illustrates many of the features stressed in the literature: aggressive impulsive behaviour, paranoid beliefs, nocturnal hallucinations and episodes of clouding of consciousness.

A boy of 15 came from a family in which two members showed pes cavus and two others were subject to attacks of depression. He developed scoliosis, ataxia and titubation of the head at 13. At 15 he became stubborn and irritable, started housebreaking and absconded from home. Four months later he tried to poison his father and bought a rope with which to hang his stepmother. Later that month he was found wandering in a state of confusion. He had been observed to behave strangely at school where, following a retrosternal 'feeling of excitement', he would bang desks and shout for several minutes, subsequently having no recollection of this behaviour. In bed he had seen visions before falling asleep, often of a diminutive man in ruffles and buckled shoes who would utter the word 'Transformation'.

On admission to hospital he showed advanced features of Friedreich's ataxia, was unhappy and tearful, and claimed that his father and stepmother were plotting against him. Attention, concentration and memory were unimpaired. During 4 months in hospital he remained paranoid and subject to sudden outbursts of rage. EEG was grossly abnormal, with theta waves predominantly in the right temporo-occipital region. Towards the end of his stay he suddenly became euphoric, denied his hatred of his family and was discharged.

He worked well as a laboratory technician for 6 months then again had a fugue-like episode. One month later he attacked his family, threw vitriol over a neighbour, and was committed to a psychiatric hospital.

Such severe psychotic pictures have sometimes been labelled 'Friedreich's psychosis'. However, it seems unlikely that they are in any way specific for the disease. Some appear to be schizophrenic illnesses, occurring in families already prone to schizophrenia, whereas others may represent the paranoid hallucinatory states of temporal lobe epilepsy.

Motor neurone disease (amyotrophic lateral sclerosis, Lou Gehrig's disease)

Motor neurone disease (MND), or amyotrophic lateral sclerosis (ALS), is a complex disorder with many variants becoming apparent as genes associated with familial forms are discovered. In the sporadic forms it is commoner in males than females and has an onset usually between the ages of 50 and 70 years. Incidence is reported at approximately 2 per 100 000 population (Yoshida *et al.* 1986). The disorder consists of a combination of muscular atrophy of lower motor neurone type together with spasticity due to corticospinal tract damage. Some forms have an accompanying dementia.

The precise clinical picture depends on the relative prominence of symptoms of upper and lower motor neurone lesions.

The onset is insidious, usually with atrophy of the small hand muscles. The thenar and hypothenar eminences are often the first to be affected. Slow progression comes to involve the arms and legs symmetrically, atrophy being accompanied by prominent fascicular twitching. Spasticity is usually most marked in the legs, with hyperactive reflexes and upgoing plantar responses. The combination of upper and lower motor neurone signs is highly characteristic, exaggerated tendon reflexes being found along with considerable muscular atrophy. There are no sensory changes and the sphincters are rarely affected.

Sometimes atrophy is seen alone without spasticity (progressive muscular atrophy). Sometimes the accent is on the bulbar nuclei from the outset (progressive bulbar palsy), with atrophy and fasciculation of the tongue, paralysis of the vocal cords and difficulty with deglutition and articulation. Lesions of the corticospinal tracts above the medulla frequently produce an added element of pseudobulbar palsy, with loss of emotional control, a hyperactive jaw jerk, and spastic dysarthria and dysphagia.

The course is invariably progressive, but the rate varies from case to case. Most patients survive for 2 or 3 years but rarely longer, death resulting from bulbar involvement or weakness of the muscles of respiration. Very occasionally patients are encountered in whom the course is unusually benign.

The pathological changes consist of degeneration of the anterior horn cells and lateral tracts of the cord with secondary gliosis. The motor nuclei of the brainstem and the pyramids in the medulla also show progressive degeneration. The motor neurones of the cord contain filamentous inclusions and dense bodies that stain with anti-ubiquitin antibodies (Leigh *et al.* 1988; Leigh 1994). Affected muscles show denervation atrophy. In the brain there may be loss of Betz cells and degeneration of the pyramidal layers of the precentral cortex. It would appear that in a considerable proportion of patients abnormal gliosis can be detected in the cortex and subcortical nuclear masses, with atrophy sometimes particularly affecting the frontal lobes (Brownell *et al.* 1970; Hudson 1981).

Approximately 10% of cases are familial and the discovery of genes causing disease in some of these families has dramatically altered understanding of this condition. However, only a proportion of familial forms have been explained by gene discoveries. Currently, using genetic linkage studies, 10 forms of MND are recognised: ALS1–ALS8, ALS with frontotemporal dementia (ALS-FTD), and ALS with frontotemporal dementia and Parkinson's disease (ALS-FTDP). ALS2 and ALS5 are transmitted as autosomal recessive and the remainder as autosomal dominant disorders. The first gene to be discovered in an autosomal dominant ALS was *SOD1*,

which encodes superoxide dismutase 1, on chromosome 21. This gene is the cause of ALS1 (Rosen *et al.* 1993). Subsequently, mutations were found in the *MAPT* (tau) gene in ALS-FTDP, in the *VAPB* (VAMP-associated protein B) gene in ALS8, in the *DCTN1* (dynactin subunit p150) gene in progressive lower motor neurone disease, in *Alsin* in ALS2 and in *SETX* (senataxin) in ALS4. Mutations in *TDP43* have been identified in familial and sporadic ALS (Sreedharan *et al.* 2008). Gros-Louis *et al.* (2006) review the genetics of ALS and Boillee *et al.* (2006) review the current understanding of the genetics for aetiopathogenesis. As it was the first to be discovered, the largest body of work relates to *SOD1* mutations. Extensive studies in cells and in animal models have led to the conclusion that the mutations result in a gain in toxic function rather than a loss of normal function of the dismutase enzyme. In motor neurones, *SOD1* mutants tend to misfold and to form aggregates. The degree of aggregation is greater in forms that show the most propensity to misfold. It is not known whether the aggregation is itself toxic: it might be a response to some other toxic property of the mutant protein. However, aggregations are a common finding in many neurodegenerative disorders and the argument that this forms a common toxicity pathway is a compelling one (Lovestone & McLoughlin 2002). Whether it is via aggregation or some other toxic property of mutant *SOD1*, ample evidence suggests that the final or proximal cause of motor neurone death is the mitochondrion (Boillee *et al.* 2006).

Another common feature across different neurodegenerative disorders is evidence for loss of neuronal function before neuronal death. MND is no exception and, like Alzheimer's disease, studies in animal models but also in brain from patients suggests axonal damage as a feature of the disease process. Axonal transport is dependent on the axonal cytoskeleton consisting of both microtubules and neurofilaments. In Alzheimer's disease and in forms of MND involving the tau gene (ALS-FTD), microtubules are the site of axonal transport disruption. In most forms of MND, however, the evidence points to neurofilaments. In both animal models and in post-mortem brain there is evidence for neurofilament accumulation, and in animals with mutations in neurofilament genes a phenotype akin to MND is induced (Boillee *et al.* 2006). Some of the other genes associated with MND, particularly the affected dynactin subunit and *VAPB*, are known to play a role in axonal transport or the axonal cytoskeleton.

Finally, MND is not only a disorder of motor neurones, although it is dysfunction in this cell group that gives rise to the classical symptoms. Microglial cells in particular are activated in MND; likewise, induction of microglial activity in mice exacerbates disease. This has led to trials in mice of agents known to modify microglial activity such as minocycline and cyclooxygenase (COX)-2 inhibitors, with varying degrees of success. Trials in humans are awaited. Many other potential therapeutic avenues are being pursued based on

experimental interventions in rodent models including trophic factors and stem cell therapies. However, only one compound, riluzole, has been approved as a disease-modifying therapy.

The treatment of MND is complex and involves a wide range of interventions for the many symptoms that result from motor neurone failure. Radunovic *et al.* (2007) review the range of care required for patients, from diagnosis, through symptomatic treatments to disease-modifying therapies and palliative care. The only specific drug approved, riluzole, increases life expectancy by at least 3 months after 18 months of treatment.

Psychiatric aspects

With the exception of cognitive impairment, the majority of patients appear to show little by way of psychiatric disturbance, except perhaps for understandable depression due to their progressive incapacitation, or emotional lability resulting from pseudobulbar palsy.

Emotional lability and loss of emotional control may be prominent when an element of pseudobulbar palsy is part of the picture. Of 101 cases, Ziegler (1930) reported explosive laughing or crying in 19, all except one of whom had signs of brainstem involvement. Several patients described clearly that their subjective emotional state was at variance with such reactions. One patient, in addition to weeping spasmodically, was prone to violent and uncontrollable outbursts of rage.

Houpt *et al.* (1977) found that one-third of their patients scored as moderately depressed on the Beck Depression Inventory, and more than one-fifth warranted a clinical diagnosis of depression at interview. Hogg *et al.* (1994) have reported the results of a questionnaire survey of 52 patients, finding high scores on the Hospital Anxiety and Depression Scale. Almost half of the sample could be considered depressed, this being significantly related to the severity of physical impairments and dependence on others. Systematic reviews suggest rates of depression of about 50% (McLeod & Clarke 2007), although Wicks *et al.* (2007) note that rates of depression depend on the scale used, finding 44% not depressed with one scale and 75% not depressed with another. Psychosocial factors play a greater role in determining depression and quality of life than physical disability in MND (Goldstein *et al.* 2006; McLeod & Clarke 2007).

Dementia is not a component of most cases of MND. Careful testing may nonetheless reveal deficits in memory and frontal lobe function, even in patients who are superficially intact (David & Gillham 1986; Irwin *et al.* 2007; Phukan *et al.* 2007). In particular, personality change, irritability and executive dysfunction syndromes characterise the deficits and neuropsychological testing suggests frontal lobe dysfunction. This overlap with frontotemporal dementia is marked in some families who present with a full FTD

syndrome in addition to MND. These families represent subtypes of the disorder, and in one set of families mutations in the same gene that is associated with FTD (*MAPT*) have been found. Mutations in this gene cause a remarkable range of disorders, from FTD, through FTD-MND variants to corticobasal degeneration and progressive supranuclear palsy. Cortical blood flow and glucose metabolism, especially in frontal areas, have been shown to be reduced on single-photon emission computed tomography and PET (Goulding *et al.* 1990; Ludolph *et al.* 1992). Using PET, Kew *et al.* (1993a,b) have demonstrated abnormal patterns of activation in prefrontal and other brain areas in response to motor tasks, this being especially marked in patients who perform poorly on frontal lobe tests.

Hudson (1981), Ferrer (1992) and Kew and Leigh (1992) review the literature on patients who develop overt dementia and/or parkinsonism along with the disease. The occurrence of dementia has recently gained increased recognition, being mostly of frontal-lobe type. Mental features of behavioural, emotional and memory disorder set in insidiously, usually some 6–12 months before wasting begins. However, the two may evolve concurrently, or the wasting may precede the dementia. The clinical picture is typical of other frontal lobe dementias except for its rapid course. The patient is characteristically euphoric and disinhibited, and restlessness and impulsivity are common. Progressive language difficulties lead to stereotyped phrases, echolalia and ultimately mutism, while perceptual and spatial functions usually remain intact. Some patients develop gluttonous behaviour and hypersexuality (Neary *et al.* 1990). In the presence of cognitive impairment the motor manifestations tend to involve the tongue and proximal upper limb muscles predominantly, while the hands and legs are spared, so that the patient remains mobile until late in the disease. A familial incidence has sometimes been noted.

The pathological changes include spongiform changes in the superficial cortical layers, and it is likely that some cases formerly classified as an amyotrophic variant of Creutzfeldt–Jakob disease were suffering from the present condition. The conjunction between ALS and parkinsonism–dementia in the island of Guam (see below) appears to be different, in particular showing the histopathological hallmark of neurofibrillary tangles.

Amyotrophic lateral sclerosis and the parkinsonism–dementia complex of Guam

Amyotrophic lateral sclerosis has been found to occur with extraordinary frequency among the indigenous Chamorro population of the island of Guam in the western Pacific (Kurland & Mulder 1954). Here the prevalence is 100 times greater than in the USA. Cases tend to occur familiarly but no clear pattern of inheritance has emerged. In the same population a syndrome characterised by parkinsonism and pro-

gressive dementia is also found (Lessell *et al.* 1962), and it is now recognised that the two essentially represent different facets of the same disease process. Both also occur in the neighbouring islands of the Mariana group and in the Kii peninsula of Japan.

The ALS is indistinguishable from the classic disease apart from its tendency to be associated with parkinsonism and dementia. The onset also tends to be at a younger age and the course more protracted. The parkinsonism–dementia complex presents with memory deficits and a slowing of mental and motor activity, and progresses to generalised dementia with extrapyramidal rigidity. Some patients develop psychotic disorders in the later stages, with delusions, hallucinations and hostile destructive behaviour.

A re-evaluation of 176 patients from Guam confirmed the close interrelationships between the two disorders (Elizán *et al.* 1966). Of the 104 who presented initially with ALS, five developed parkinsonism–dementia complex on average 5 years later, five developed parkinsonism alone and two an organic mental syndrome without parkinsonism. Of the 72 who presented with parkinsonism–dementia complex, 27 developed ALS on follow-up. In the families concerned, ALS and parkinsonism–dementia complex often occurred indiscriminately and in various combinations, giving further evidence of a close relationship between the two syndromes.

The histological pictures similarly show a good deal of overlap. The parkinsonism–dementia complex shows diffuse cerebral atrophy with widespread neurofibrillary changes in the cortex and subcortical nuclei. Atrophy of the globus pallidus is characteristic, also loss of pigment from the substantia nigra (Hirano *et al.* 1961). The cases with ALS show similar neurofibrillary changes throughout the brain in addition to the classic cord pathology (Hirano *et al.* 1966). Patients who have shown clinical features of only one syndrome are commonly found to show the pathological changes of both.

Myasthenia gravis

Myasthenia gravis is a disorder of the voluntary musculature characterised by abnormal muscle weakness after activity and a marked tendency for recovery of power after a period of rest. It is commoner than chance among patients who have had hyperthyroidism, Hashimoto's thyroiditis or other autoimmune disorders. Thymic abnormalities are usually present in the form of thymus hyperplasia, thymic tumour (thymoma) or more rarely thymus involution. More than two-thirds of cases show characteristic thymic changes, with large germinal centres in the medulla, indicative of B-cell activation and proliferation. There is now abundant evidence that the disease is essentially an autoimmune disorder in which circulating antibodies interfere with motor end-plate function. The disorder was first recognised in the seventeenth century, although the first full descriptions of the

syndrome were made much later. Hughes (2005) reviews the fascinating history of a remarkable disease.

Clinical features

The disorder can begin at any age, usually appearing in the second or third decades but with evidence for bimodal distribution of onset with peaks before and after the age of 50 years. It is more frequent in females than males (ratio approximately 6:4) until late middle age when the sex ratio is reversed. The prevalence in the population is increasing, probably due to increased survival, and is on the order of 80 per million (Phillips 1994; Flachenecker 2006).

The neurological syndrome is extensively described elsewhere. In brief, the first complaint is usually of ready fatigability of certain muscle groups, or some symptom of cranial nerve involvement such as diplopia, difficulty with chewing or difficulty with swallowing. The onset is sometimes insidious, sometimes sudden, and precipitation by emotional upset or a febrile illness is not uncommon. Ocular muscles are usually involved early leading to ptosis or diplopia. Bulbar symptoms are also common, with difficulty in chewing or swallowing which worsens as the meal progresses, or a characteristic fading and slurring of speech after speaking for several minutes. Facial weakness may produce flattening and loss of wrinkles and the smile may have a characteristic 'snarling' quality. The muscles of the neck are often involved, also the shoulder girdles and flexors of the hip. In general, proximal muscle groups are more severely affected than distal groups, and the arms more than the legs, but the distribution is variable. The respiratory muscles may fatigue easily on laughing or crying, and in crises of the disorder respiration can be dangerously embarrassed.

The muscular weakness is typically variable from day to day and sometimes from hour to hour. It tends to be worse towards the end of the day, but is sometimes paradoxically most marked on waking in the morning. Ultimately, weakness of certain muscle groups may persist even when these have not been exercised for some time. Wasting is occasionally observed. The tendon reflexes almost always remain brisk even when weakness is severe, but may decrease on repeated elicitation. Objective sensory changes are absent but the patient may experience pain in the muscles of the neck and around the eyes, or complain of a feeling of stiffness or paraesthesiae in affected areas.

The course is extremely variable. It is usually slowly progressive but a number of cases prove to be relatively static. Spontaneous remissions and sudden relapses may occur. Diagnosis is by a combination of clinical evaluation and diagnostic tests, including demonstration of autoantibodies to acetylcholine receptors (AChRs) and muscle-specific tyrosine kinase (MuSK) and observation of the response to anticholinesterase drugs. Edrophonium chloride may be injected intravenously, with examination for increased muscle

strength during the following 30–60 seconds. Electrophysiological tests include demonstration of an abnormal decrement in compound muscle action potentials on repetitive motor nerve stimulation, or the more sensitive single-fibre electromyography which shows blocking or abnormal 'jitter' (i.e. variations in interpotential intervals).

It is important to perform tomograms of the anterior mediastinum to detect thymic hyperplasia or the presence of a malignant thymoma, also chest radiography to exclude bronchial carcinoma leading to Lambert–Eaton syndrome (see below).

Pathophysiology

Myasthenia gravis has proved to be essentially an autoimmune disorder: antibodies are present at the neuromuscular junction, where the pathology occurs; antibodies from patients and immunisation against the antigen induce disease in experimental animals; and therapies that remove the antibodies are successful in relieving disease (Conti-Fine *et al.* 2006). The antibodies are of two main types, the most common being against nicotinic AChRs and an MuSK involved in AChR clustering. The biochemical defect at the neuromuscular junction was first thought to be due to competitive blocking by circulating antibodies that impaired the effects of acetylcholine at the motor end-plate. It is now apparent that there is considerable damage to AChRs at the postsynaptic membrane of the neuromuscular junction, brought about by antibodies directed against them (anti-AChRs). This damage is likely induced largely by complement activation, with evidence for a range of complement proteins including the activation fragment of C3 and the membrane attack complex being present in both patients and animal models (Conti-Fine *et al.* 2006; Vernino 2007). Other mechanisms include cross-linking of the AChR leading to degradation and functional blockade.

Cultures of thymic lymphocytes from myasthenic patients produce anti-AChR antibodies *in vitro*, particularly those from patients with thymic follicular hyperplasia showing active medullary germinal centres (Ragheb & Lisak 1994). Moreover, certain elements within the thymus share strong structural and antigenic similarities with muscle AChRs. It is therefore possible that an early step in pathogenesis consists of sensitisation of anti-AChR antibodies within the thymus itself. In this way evidence can be assembled to suggest that the thymus is involved not only in perpetuating the disease but perhaps in inducing it as well (De Baets & Kuks 1993). Approximately 10–15% of patients have a thymoma (Tormoehlen & Pascuzzi 2008).

Treatment

Anticholinesterase drugs remain the mainstay of treatment for patients with mild myasthenia or symptoms restricted to

a small group of muscles. More recent developments are summarised by Conti-Fine *et al.* (2006). Corticosteroids and other immunosuppressants are essential components of therapy. Plasma exchange (plasmapheresis) and intravenous immunoglobulin are used for severe exacerbations and thymectomy is a therapeutic option, although the evidence base for this is not as strong as it might be. Psychiatric supervision can have an important part to play in patients who develop marked psychological reactions to the disorder. As discussed below the emotional state of the patient may have a considerable influence on clinical progress.

Other myasthenic syndromes

Other myasthenic syndromes may be induced by certain drugs, notably phenytoin, streptomycin and penicillamine. The latter in particular may be associated with a rise in anti-AChR antibodies and does not resolve when the penicillamine is withdrawn. Transient neonatal myasthenia may occur in children born to myasthenic mothers, usually resolving within weeks or months. Congenital myasthenia may be present from birth or become apparent during the first 2 years of life. Juvenile myasthenia can begin at any age from 12 months to 16 years and is generally similar to the adult disease. Lambert-Eaton syndrome is often associated with neoplasia, especially oat-cell carcinoma of the bronchus, sometimes developing several years before the neoplasm is apparent. Perhaps one-third of cases are non-neoplastic. Weakness and wasting, usually insidious, affect the proximal parts of the limbs and trunk, and ptosis and diplopia are not uncommon. Fatiguability is usually less striking than with myasthenia gravis, and autonomic symptoms such as dry mouth are common. Other differences are that the tendon reflexes are diminished or absent but reappear following a sustained muscular contraction, and there may be a 'reversed myasthenic effect' with progressive augmentation of strength during the first few seconds of maximal effort (Erlington & Newsom-Davis 1994). Circulating antibodies to AChRs are absent, but there is evidence of an IgG autoantibody that binds to voltage-regulated calcium channels at neuromuscular junctions. Anti-cholinesterase drugs lead to little improvement, but guanidine and 3,4-diaminopyridine are of benefit. Prednisone, azathioprine and plasma exchange may be useful in non-neoplastic cases.

Psychiatric aspects

Myasthenia gravis has attracted psychiatric attention on several grounds. Emotional factors have been thought to precipitate onset in some cases and to play a significant role in aggravating the established disease in others. The psychological make-up of myasthenic patients and their responses to the illness have accordingly been studied in some detail. There is also a possibility that memory may be adversely affected in certain patients. Finally, important problems of differential diagnosis not infrequently arise, and can involve psychiatric as well as neurological disorders.

The psychological responses seen in the illness are discussed by MacKenzie *et al.* (1969), Sneddon (1980) and Kulaksizoglu (2007). The patient is faced with the task of

adapting to a disease that produces neither physical deformity nor pain and which has ephemeral manifestations. Interpersonal difficulties may be aggravated by the anxiety and uncertainty which the symptoms evoke, and by the tendency for those around to become suspicious of the genuineness of the disorder when there is so little to observe objectively. Patients may be suspected of faking their weakness or of being drunk when the speech is slurred. Meeting strangers can be a source of social embarrassment when facial weakness prevents a smile, likewise eating in public when the jaw must be supported towards the end of a meal.

The individual's reaction to the disease appears to be closely related to his premorbid personality and shows the usual range of responses to physical incapacity (Magni *et al.* 1988). Anxiety can be very marked and the patient's life may come to centre around the schedules of medication. An increase in the dose is regarded as ominous while a decrease leads to fearfulness of symptoms returning. Other patients seek to deny their disability, reducing medication and embarking on too much activity. The dependency induced by the disease often sets in train further psychological reactions. Some patients regress and develop increasing dependence on relatives and doctors. An obsessional attendance on every detail of treatment may result. Others become severely depressed, or hostile and frustrated. Major mental illnesses may occasionally arise with sporadic case reports of co-occurrence of psychosis and myasthenia.

Some, but by no means all, patients report precipitation of crises or exacerbation by emotional stress (Bedlack & Sanders 2000). Specific emotional factors can often be discerned in close relation to the first appearance of symptoms, probably as a result of their aggravating the latent disorder and bringing it to attention. Oosterhuis and Wilde's (1964) study of 150 cases showed that 8% had had some acute emotional disturbance directly preceding the onset. A further one-third had had a fairly long-lasting period of emotional stress coexistent with the onset, such as difficulties at work or marital infidelity. Two-thirds of these patients reported that emotional disturbances worsened their symptoms but one-third were either uncertain or denied an effect of stress or emotion.

Sneddon's patients had often needed to learn techniques for handling anger-provoking situations in order to remain well (Sneddon 1980). For example, half left the room and lay down if they felt themselves becoming angry; others found that crying and swearing relieved the tension and caused less weakness.

Paul *et al.* (2001) reviewed studies of cognition in myasthenia gravis and found none that met at least half of their criteria for study inclusion. However, despite this they conclude that there is some (weak) evidence for mild impairments in learning, although they note that patients frequently complain about cognitive difficulties.

Psychiatric aspects of differential diagnosis

Myasthenia gravis must be distinguished from other neurological disorders including ocular and peripheral neuropathies, brainstem lesions, parkinsonism, MND and carcinomatous myopathy. From the psychiatric point of view mistakes may occur in both directions: patients with weakness and fatigue of neurotic or depressive origin may be suspected of the disease; conversely, patients with myasthenia gravis may initially be diagnosed as suffering from neurosis, conversion hysteria or personality disorder.

Complaints of weakness and excessive fatigue are commonly encountered in routine medical practice and many such patients are mistakenly suspected of myasthenia gravis. Grob (1958) estimated that 20% of patients referred to him as possible myasthenics were in fact suffering from emotional disorders. Schwab and Perlo (1966) in an analysis of 130 patients wrongly diagnosed as having myasthenia gravis, found that by far the greatest proportion (38%) were suffering from a 'chronic fatigue syndrome' attributable to some form of neurosis. Such a mistake is particularly likely to arise when an injection of neostigmine or edrophonium has produced a marked placebo response, and especially if the patient's report of improvement has not been backed by attempts to monitor muscle strength objectively. Sometimes improvement on oral medication alone is accepted as evidence of myasthenia and this can be seriously misleading.

Progressive muscular dystrophies

The progressive muscular dystrophies, or myopathies, comprise a group of genetically determined degenerative diseases primarily affecting the voluntary musculature. Reviewed comprehensively by Emery (2002), one classification system is based on the clinical picture with the distribution of weakness determining the categories of Duchenne and Becker type, Emery–Dreifuss, limb-girdle, facioscapulohumeral, distal and aculopharyngeal.

Clinical features and genetics

The Duchenne, and milder Becker, forms result from mutations in the dystrophin (*DMD*) gene on the X chromosome, most commonly exon deletions. It develops very occasionally in girls when there is a translocation between the short arm of the X chromosome and some other chromosome; a variant resembling limb-girdle dystrophy may also be seen in female carriers when one X chromosome is partially inactivated ('lyonisation'). Female carriers of the disease can be detected by DNA studies, complemented where necessary by serum creatine kinase estimations. Prenatal diagnosis of affected male fetuses is possible (Kemper & Wake 2007). While there are no curative therapies at present, exciting

progress towards molecular interventions are being made (Cossu & Sampaolesi 2007; Wagner *et al.* 2007).

Duchenne dystrophy becomes apparent towards the end of the third year of life with difficulty in walking and climbing stairs, first affecting the pelvic girdles but soon the shoulder girdles as well. Enlargement of the calf muscles is characteristic, also sometimes affecting the quadriceps and deltoids. Most patients are unable to walk by the age of 10 and become confined to a wheelchair. Progressive skeletal deformity tends to develop as a result of atrophy and contractures. Death usually occurs from respiratory infection or cardiac failure; formerly few patients survived the second decade, but with modern supportive care many now live to their late thirties. Myocardial involvement is invariable but may not be detectable in the early stages. Characteristic changes are seen in the ECG in a high proportion of cases.

The Becker form of dystrophy affects muscle groups in a similar distribution but is more benign. Onset is usually between the ages of 5 and 25 years and patients may remain ambulant for two or three decades. Though severely disabled some can survive to a normal age. It is about one-third as common as the Duchenne form in incidence at birth, and is due to different defects in the same gene.

Facioscapulohumeral dystrophy is the third most common dystrophy and occurs equally in males and females, with onset at any time between childhood and late adult life. The facial and scapulohumeral muscles are the first affected, leading to winging of the scapulae and marked facial weakness that gives a characteristic pouting appearance. Muscular hypertrophy is uncommon. Spread may occur elsewhere, particularly to the anterior tibial muscles producing foot drop. Progression is variable, sometimes leading to severe disability after 20–30 years but sometimes following a benign course with periods of apparent arrest. It is inherited as an autosomal dominant disease, with the locus on chromosome 4. Interestingly, the mutation is not in a gene but in a DNA tandem array called D4Z4 where a deletion causes a frameshift disruption in downstream genes (van der Maarel & Frants 2005).

Distal muscular dystrophy is inherited as both an autosomal dominant and a recessive form, with onset usually in middle age. Weakness begins in the small hand muscles and lower legs then gradually spreads proximally. Rates of progression are variable.

Limb-girdle dystrophy affects males and females equally, usually beginning in the second or third decades but sometimes as late as middle age. It is due to an autosomal recessive gene, but sporadic cases are common. Either the shoulder or the pelvic girdles may be affected initially, and enlargement of the calf muscles sometimes occurs. Distinction from the Becker form can be made by muscle biopsy with dystrophin staining. The rate of progression is variable but severe disability is usually present after 20 years.

Oculopharyngeal muscular dystrophy occurs especially in French Canadians and has been traced to immigrants from France in the seventeenth century (Emery 2002). It is due to a GCG expansion in the N-terminal part of the gene for poly(A) binding protein nuclear 1 (PABPN1) at 14q11.2–q13. The Emery–Dreifuss form occurs as autosomal dominant and recessive forms, both being associated with mutations in the gene encoding lamin A/C.

In all varieties the tendon reflexes are diminished or lost in relation to affected muscle groups. All forms of sensation are intact. Histologically, the affected muscles show great variation in the size of individual fibres and a large amount of connective and adipose tissue.

Psychiatric aspects

From the psychiatric point of view the issue that has attracted most attention concerns cognitive function in muscular dystrophy, not least because of interest in the function of some of the dystrophy-associated genes in normal brain (Mehler 2000; D'Angelo & Bresolin 2006). There are obvious difficulties in attempting to assess the intellectual potential of children with severe physical handicaps, and in deciding whether decreased educational performance should be attributed to neurobiological dysfunction or to the psychosocial consequences of physical disablement. Nevertheless, evidence increasingly favours the view that a substantial proportion of patients with the Duchenne form have learning deficits and cognitive dysfunction. There are also indications that this may sometimes reflect cerebral involvement as part of the disease.

In a moderately sized series of patients with facioscapulo-humeral dystrophy, clear evidence was found of mild learning difficulties, with severity being associated with the extent of the molecular genetic lesion (Sistiaga *et al.* 2008). A deletion resulting in a fragment size of 24 kb or less gave rise to significantly reduced IQ and visuospatial and other deficits compared with patients with molecularly confirmed but less severe genetic variants. There was no correlation with muscle phenotype. Young children with the Duchenne type show a wide range of, usually, mild cognitive impairments and learning difficulties (Wicksell *et al.* 2004; Cyrulnik *et al.* 2007, 2008; Young *et al.* 2008). Some have attributed these mild changes to cerebellar damage (Cyrulnik & Hinton 2008). However, some patients have severe learning difficulty and there is some evidence for a genotype–phenotype correlation, with severe impairment being related to deletions in the distal part of the gene (Moizard *et al.* 2000; Giliberto *et al.* 2004). Functionally there is evidence for abnormality in the EEG, and in both structural and functional imaging (Rae *et al.* 1998; Mercuri *et al.* 1999; Anderson *et al.* 2002; Quijano-Roy *et al.* 2006; la Coletta *et al.* 2007). Together these data argue for a role, especially for dystrophin, in the normal brain. Animal models with perturbed dystrophin show alteration

in long-term potentiation, the cellular basis of plasticity and perhaps learning and memory, supporting this hypothesis (Anderson *et al.* 2004; Vaillend *et al.* 2004).

Other, non-cognitive symptoms are also found. In a series of patients approximately one-third had a lifetime incidence of psychiatric comorbidity, most often depression or phobias (Kalkman *et al.* 2007). However, there was no phenotype–phenotype correlation either between type of dystrophy or with severity of symptoms. Attention-deficit hyperactivity disorders and other disorders including autism occur more frequently in Duchenne than expected from population rates (Hendriksen & Vles 2008; Young *et al.* 2008).

As adulthood approaches the psychosocial consequences of the disorder increasingly intrude, and the patient's psychological adjustment will often be decisively shaped by the milieu in which he lives. The strain thrown on the families of affected individuals may then be very considerable.

There does not appear to be any special association between non-myotonic forms of muscular dystrophy and psychosis, although occasional families have been reported in which schizophrenia and muscular dystrophy appear to coincide.

Myotonic dystrophies

In the myotonic dystrophies a variable degree of muscle wasting and weakness is combined with the phenomenon of 'myotonia', i.e. delayed relaxation of skeletal muscles after voluntary contraction. The commonest is myotonic dystrophy (dystrophia myotonica, Steinert's disease), in which the myotonia is accompanied by progressive wasting and weakness of selected muscle groups together with other characteristic features such as cataract, hypogonadism and frontal baldness. Myotonia congenita (Thomsen's disease) is a more generalised muscle disorder with myotonia and hypertrophy, setting in very early in life but rarely progressing to serious disablement. Paramyotonia congenita is similar but with the myotonia and weakness appearing only on exposure to cold. Other myotonic disorders include a variant of myotonia congenita with onset later in childhood, and various forms of periodic paralysis which also show myotonic features.

Dystrophia myotonica

The molecular genetics of dystrophia myotonica has revealed a fascinating new molecular pathogenesis of disease, that due to abnormality in RNA resulting from unstable repeat expansion of regions of DNA (Day & Ranum 2005). There are two forms: type 1 (DM1) resulting from an expanded CTG repeat in the 3' non-coding region of the myotonic dystrophy protein kinase (MDPK) gene on chromosome 19q35, and type 2 (DM2) resulting from an expanded CCTG repeat in an intron in the zinc finger protein 9 (ZNF9) gene on chromo-

some 3q21. These expansions may be very large indeed, from 37 to thousands in the case of DM1 and from 75 to 11 000 in DM2. Previously, repeat disorders were thought to be only due to triplet repeats, as for Huntington's disease, and were thought to exert their pathogenicity through loss of function of the primary gene or a toxic gain of function due to novel or aberrant protein expression. DM2 demonstrated that the unstable repeat expansions can be tetranucleotide (and indeed pentanucleotide as in the case of spinocerebellar ataxia type 10) and also raised the possibility for the first time of RNA-dominant disease (Osborne & Thornton 2006). All repeat expansion diseases show the phenomenon of anticipation, i.e. increasing severity and earlier onset in successive generations due to germ-cell instability of the expansion resulting in ever larger expansions with each generation. In DM1 this instability is greater in maternal transmission. Transmission patterns are less clear in DM2; although intergenerational expansion is more dramatic than in DM1, the picture is complicated both by somatic mosaicism and by the fact that the effect of expansion size is saturable such that the genotype–phenotype correlation is not as clear-cut as for DM1 (Day & Ranum 2005).

The pathogenetic effects of these two mutations is not fully understood, although much progress has been made. Both expansions are transcribed into RNA but are not translated into protein, ruling out the possibility of a toxic gain of function from a novel protein. Haploinsufficiency of the *MDPK* and *ZNF9* genes themselves was a possibility but the absence of other mutations in these genes and the apparent normality of mice lacking *MDPK* weigh against this potential mechanism (Day & Ranum 2005). Nor do other, nearby, genes in the DM1 or DM2 loci seem to be affected or indeed similar to each other, making a localised effect on gene expression unlikely. Instead, a so-called transdominant effect of RNA seems to be active, the RNA produced regulating other, distant, genes and resulting in the complex clinical picture. The genes affected in DM1 include cardiac troponin T, the insulin receptor, a muscle chloride channel (CLC-1), tau and the *N*-methyl-D-aspartate (NMDA) NR1 receptor, all of which show abnormal splicing in the presence of CUG or CCUG expansion, which in turn alter the regulation of RNA-binding proteins (Day & Ranum 2005; Osborne & Thornton 2006). The alteration in splicing of these genes and the subsequent change in protein expression patterns in both brain and peripheral tissue explains many of the known features of the diseases.

Clinical features

DM1 and DM2 show substantial clinical overlap. The disease is characterised by muscle weakness and myotonia together with multisystem effects in eye, cardiac, central nervous and endocrine systems. Males and females are equally affected. The commonest age of onset is between 20 and 25, and 50% of patients will have developed the disorder by this age.

However, the range covers virtually the whole lifespan as described above. Congenital forms of DM1 are often heralded by pregnancy complications and the children have severe disease accompanied by craniofacial abnormalities. Congenital or juvenile DM2 has not been reported.

The myotonia is usually the first symptom to be declared but is rarely sufficient in itself to lead to medical attention. It chiefly affects the hands, forearms and orbicularis oculi, although the legs may be implicated as well. It is best demonstrated by observing the slowed relaxation of hand grip, or the difficulty in opening the eyes after screwing them up tightly. Delayed relaxation may be noted in the tendon reflexes, or a groove may persist in the tongue after depressing it with a spatula. The smile is sometimes characteristically slow and lingering.

The myotonia is rarely a grave handicap. Involvement of the tongue can cause difficulties with articulation, or sudden falls may result from difficulty in adjusting balance after a trip or stumble. Aggravating factors include exposure to cold or prolonged inactivity. It is characteristically worse on waking and improves as the patient begins to move about. Caughey and Myrianthopoulos (1963) also stress that it is often aggravated by emotional factors such as fright or surprise. One of their patients first noticed the myotonia when his legs seemed to freeze while caught in a burning building, and another when his legs became stiff on the signal to start a race. Fear, anger or sudden joy may temporarily increase the symptoms so that a wave of stiffness is felt to run through the muscles of the body. Another patient was liable to fall rigidly to the ground whenever she was suddenly excited or surprised. Several had become housebound because of fear of falls in the street.

The atrophy and weakness is selective, symmetrically affecting the facial muscles, masticatory muscles, sternomastoids and distal parts of the arms and legs. Hypertrophy can occur in the early stages but atrophy usually prevails. The facial appearance is characteristic, with hollow temples, ptosis, a sad lugubrious expression and a tendency for the mouth to hang partially open. Finger grip is weak and foot drop may occur. The tendon reflexes are normal initially, though diminished or absent as the disease progresses. Sensory changes are rare, but slight sensory disturbances and subjective complaints of pain are occasionally encountered. The pattern of weakness does show some differences between disease types. DM1 cases typically show facial, masticatory and upper limb weakness followed by shoulder and hip girdle involvement, whereas DM2 often presents with hip girdle problems manifested as difficulty in rising or climbing stairs (Day & Ranum 2005).

The progression of the disability is remarkably variable but usually slow. Rare cases may be completely disabled within a year or two, although most patients remain ambulant for 15–20 years or even longer. In general the muscle weakness and wasting will be much less severe in cases of

late onset, and the prognosis can then be remarkably good. In the final stages respiration and swallowing may become embarrassed.

On pathological examination the affected muscles show variation of fibre size, fibrosis and fibre degeneration as in other dystrophic processes. A characteristic finding is multiplication of sarcolemmal nuclei, which tend to form long central chains, also sarcolemmal aggregates of mitochondria. Changes have been detected in muscle spindles, with abnormal innervation to the intrafusal fibres and abnormally shaped end-plates.

Associated defects may involve a number of organs and systems of the body. Cataract is one of the commonest additional defects: in some series slit-lamp examination has revealed lens opacities in almost every case. Other ocular abnormalities may include limitation of eye movements, retinal degeneration or partial constriction of the visual fields. Frontal baldness is common in males and occasionally occurs in females. Endocrine abnormalities include testicular atrophy and hypogonadism in the male, and menstrual abnormalities and infertility in the female. Insulin resistance is common and pituitary–adrenal and thyroid abnormalities have occasionally been reported.

Electrocardiographic abnormalities are found in more than half of patients, including varying degrees of heart block and atrial dysrhythmias. Cardiac failure or sudden death due to cardiac arrest may occur. Smooth muscle dysfunction can involve dilatation of the lower oesophagus, peristaltic incompetence of the small intestine, dilatation of the colon, or a flaccid bladder with urinary retention. Anaesthetics present a special risk, particularly of prolonged respiratory arrest following thiopental. Serum immunoglobulins are often abnormally low. Skull radiography may show general thickening of the vault, localised thickening of the frontal bones (hyperostosis frontalis interna), enlarged sinuses or a small sella turcica. Other congenital physical defects include a high narrow palate, hare lip or talipes equinovarus.

Differential diagnosis and treatment

Differentiation from other forms of muscular dystrophy is important on account of the differing prognosis. It can usually be made on the basis of the characteristic distribution of weakness, wasting and myotonia, together with associated abnormalities in other systems as outlined above. The facial appearance may resemble that of facioscapulohumeral dystrophy, although there the limbs are affected proximally rather than distally. Myasthenia gravis may be suspected when ptosis and muscular fatigue are marked. Differentiation from myotonia congenita (see below) can be more difficult when onset is early in life, and indeed the two have sometimes been reported from the same family. Polyneuropathy may be suspected in view of the distal and symmetrical weakness. Peroneal muscular atrophy can usually be distin-

guished by the associated loss of vibration sense at the ankles.

Psychiatric aspects

Involvement of the CNS is undoubted in the more severe early-onset and congenital cases but likely in adult-onset cases also. In congenital DM1, myotonia and cardiovascular involvement may be absent and cerebral effects predominant or may be the only symptoms. Mental impairment is common: IQ levels are between 40 and 80 in 50–90% of patients (Meola & Sansone 2007). Speech is delayed and a range of behavioural symptoms are reported including hyperactivity, autism and various difficulties in social behaviours (Steyaert *et al.* 1997). In the juvenile form of DM1, CNS effects are predominant and motor signs are typically weak or absent. Learning disabilities and difficulties with relationships with peers occur in school-age children. Attention deficit hyperactivity disorder in preschool children and anxiety disorders in childhood and young adulthood are common (Meola & Sansone 2007).

Adult-onset disease shows more neuropsychological involvement in DM1 than DM2, although in both types cognition, behaviour and personality changes may occur together with fatigue and daytime sleepiness. Meola and Sansone (2007) review the evidence for neuropsychiatric symptoms.

In the absence of frank mental retardation it is uncertain how much global intelligence is affected by DM1 or DM2. A series of studies report low-normal range IQ, although Meola and Sansone (2007) do find abnormally low IQ in those with moderately severe DM1. On the other hand, visuospatial defects undoubtedly do occur in DM1 and may be invariable. Speech is often affected due to motor difficulties but language itself is normal. Malloy *et al.* (1990) carried out a careful study of 20 patients between the ages of 20 and 65, stratified with regard to age and compared with controls matched for age and education. While the sample as a whole showed cognitive deficits, especially on non-verbal spatial tests, there was no evidence of an abnormal age-related decline. In contrast to the motor deficits, which clearly progressed, the cognitive impairments appeared to be relatively stable. Bird *et al.* (1983) could not document definite decline in any of their 29 patients, and there was no deterioration on repeat psychometric testing in five cases after intervals of 11–19 years.

Dysexecutive syndrome, i.e. reduced initiative and activity, is a feature of DM1 and various studies have shown selective involvement of frontal lobe function. Apathy is common.

Personality abnormalities and social deterioration are perhaps even commoner than defective intelligence. However, Bird *et al.* (1983) have warned against stereotyping sufferers from the disease. They examined 29 patients and found that one-third showed prominent personality abnormalities, mainly in the presence of low intellectual ability and advanced

physical handicap. However, there was no 'typical' personality type, and the problems that emerged were largely what would be expected in persons with physical and cognitive problems. Subsequently, however, two studies reported avoidant personality traits to be particularly characteristic of DM1 and to be associated with neuroimaging evidence of disease in frontal and parieto-occipital regions (Delaporte 1998; Meola *et al.* 2003).

Somnolence may be a marked feature in the disease, adding to the impression of apathy and perhaps related to diencephalic dysfunction or alveolar hypoventilation. If anything patients tend to minimise the degree of somnolence. True fatigue is also prominent in many cases and goes beyond that expected from the myotonia.

The social decline that can result is usually severe and could be traced in 70% of Thomassen's (1948) patients. Caughey and Myriantopoulos (1963) encountered several families of distinction where the disease, within two or three generations, had led to a marked deterioration in family fortunes and social status. Perron *et al.* (1989) documented the socioeconomic impact of the disease in the Saguenay-Lac-Saint-Jean region of Quebec where it occurs with remarkable frequency. A representative sample of 218 affected persons over the age of 15 was compared with control data from the same population; only 12% were employed compared with 42% of controls, and the mean income for 1982 was reduced by almost two-thirds. The effect on the families was not surprisingly severe: 43% were living below the poverty line, which was three times as common as in Canadian families generally.

Myotonia congenita

Thomsen (1876) gave a clear account of the disease that bears his name in four generations of his own family. Thomassen (1948) subsequently collected all cases in the literature and described three further families, resulting in a total of 157 families with 470 affected persons. It is nevertheless a rare disease (Colding-Jorgensen 2005; Heatwole & Moxley 2007). The pattern of inheritance is usually autosomal dominant, although an autosomal recessive form has also been described. In both the dominant and the recessive forms mutations in the *CLCN1* gene coding for the skeletal muscle chloride channel CLC-1 have been found (Koch *et al.* 1993), including in Thomassen's own family (Steinmeyer *et al.* 1994). Males and females are affected equally.

Onset is usually from shortly after birth and few cases appear after the age of 12. Myotonia is typically the presenting feature and the sole cause of disability for many years. It presents as a painful stiffness or cramp on attempting voluntary movement, most marked after rest and especially troublesome first thing in the morning. The myotonia is widespread throughout the body muscles, unlike its regional distribution in dystrophia myotonica. Involvement of the

tongue and jaw may lead to difficulty with speech, chewing and swallowing. Clumsiness on initial movement may lead to frequent falls. Exposure to cold aggravates it, also excitement, tension or emotional disturbance. Most patients find that with repeated movements the stiffness passes off and learn such manoeuvres as limbering up to run.

Generalised muscular hypertrophy is common and atrophy rare. However, the strength is not proportional to the size of the muscles and patients fatigue easily. The tendon reflexes are usually normal. The associated features seen in dystrophia myotonica are rarely encountered, and when present tend to be minimal. Occasional cases have been reported with cataract, minor lens opacities or endocrine disturbance, but it is hard to be sure that these were not cases of early dystrophia myotonica without atrophy.

The course tends to remain static over the years and progression of myotonia or muscular weakness is rarely observed. The disorder is quite compatible with survival to old age. However, the myotonia is often severe and can require treatment with phenytoin or tocainide.

Psychiatric aspects

Patients with myotonia congenita are usually normal in intelligence and personality. In sharp contrast to dystrophia myotonica, social deterioration was not observed in Thomassen's (1948) large study. Mental changes were conspicuous by their absence. Thomsen (1876) himself drew attention to a hereditary psychosis in several members of his own family, describing it as a 'kind of imbecility, confusion of ideas combined with a tendency for the mind to wander and vacant brooding; it has most in common with a certain kind of mental weakness which occurs in old age'. Since then, however, most investigators have dismissed any association with psychosis as fortuitous, and in fact there are strong indications that the myotonia and the mental disorder were transmitted independently in different branches of Thomsen's family (Caughey & Myriantopoulos 1963; Johnson 1967). Johnson (1967) has reported a patient with myotonia congenita who developed two acute psychotic episodes of mixed affective and schizophrenic type. Two of the siblings had myotonia congenita, and the father and several other family members had had acute psychoses; but here again the muscle disorder and the psychotic propensity appeared to be transmitted independently in the family, and no direct relationship could be established between the two disorders.

Paramyotonia congenita

Paramyotonia congenita of Eulenburg resembles myotonia congenita except that the myotonia and weakness only appear on exposure to cold. It is transmitted as an autosomal dominant disorder due to mutations in the gene for the α -subunit of the human skeletal muscle sodium channel gene

(SCN4A) on chromosome 17 (Ptacek *et al.* 1992). Interestingly, mutations in the same sodium channel gene give rise to other paramyotonia without cold induction (Koch *et al.* 1995) and in a family with hypokalaemic periodic paralysis (Davies *et al.* 2001). Typically, paramyotonia congenita develops early in life, worsens at puberty, then tends to improve or vanish in later decades (Caughey & Myrianthopoulos 1963). It often principally affects the muscles of the face, tongue and hands. Involvement of the legs may cause 'cramps' or inability to rise from a sitting position in the cold. Severe weakness is sometimes induced by cold, with or without myotonia, and lasts on rare occasions for several hours at a time. In severe attacks the patient may be bedridden and unable to turn, leading to a suspicion of hysterical paralysis. There is no hypertrophy of muscles, and power and reflexes are normal between attacks. Psychiatric and social complications appear to be as rare as in myotonia congenita. Associated dystrophic features such as cataracts, testicular atrophy and changes on skull radiography do not occur.

Neuropsychiatric manifestations of carcinoma

Increasing attention is being paid to several neuropsychiatric syndromes that may accompany neoplasia in various parts of the body even when there is no spread of tumour cells to the brain. Thus patients with carcinoma may develop marked nervous system pathology while the tumour remains confined to its original site or when spread is limited to metastases to the regional lymph nodes. Mental symptoms figure prominently in such syndromes as well as neurological defects.

The mechanisms underlying such remote effects remain uncertain. Especially puzzling has been the observation that neuropsychiatric manifestations may precede clinical evidence of the primary tumour by a considerable period of time, sometimes several years. Moreover, the disorders may continue to progress after apparently successful eradication of the neoplasm. Occasionally, they make a first appearance some time after removal of the tumour and without evidence of recurrence of the neoplasm itself.

Before considering these remote effects in detail certain aspects of the orthodox involvement of the nervous system by secondary metastatic deposits are briefly considered.

Metastatic involvement of the CNS

Tumours that commonly metastasise to the brain include those of the lung, breast, alimentary tract, prostate and pancreas. Carcinoma of the lung is undoubtedly the most frequent variety today. Melanomas may similarly metastasise to the CNS. Secondary cerebral deposits are usually multiple and fast-growing, but occasionally a solitary cerebral metastasis may warrant surgical intervention along with treatment

of the primary growth. Not infrequently an intracranial metastasis gives rise to symptoms before the primary lesion, especially when this is in the lung, and sometimes the primary lesion is not discovered until post-mortem.

An 'encephalitic' form of metastatic carcinoma may very occasionally be encountered. Here there is no tumour formation as such within the brain but diffuse infiltration of carcinomatous cells throughout the CNS, i.e. within the brain parenchyma and along the perivascular spaces as well as in the meninges. There is no true inflammatory reaction but the presentation may at first closely simulate an encephalitic process. Carcinomatosis of the meninges may also produce a misleading picture. Secondary deposits invade the leptomeninges diffusely, particularly at the base of the brain, giving rise to an illness which at first resembles meningitis. Pyrexia and neck stiffness may be prominent features. Headache is usually marked and accompanied by cranial nerve palsies and often visual failure. A period of vague ill health has usually preceded more definite manifestations.

Non-metastatic manifestations of neoplasia (paraneoplastic disorders)

The number of non-metastatic syndromes known to be causally related to cancer is now considerable and includes sensory and other peripheral neuropathies, subacute cerebellar degenerations, myelopathies and myopathies (Grant 2002). For some time it was thought that pathological changes were restricted to levels caudal to the basal ganglia, but cerebral involvement is now recognised as well. Severe involvement of the limbic areas on the inferomedial surfaces of the temporal lobes is a well-recognised syndrome, producing an illness with prominent memory disturbances and often some degree of dementia.

Obviously, the clinical pictures that characterise these non-metastatic complications are many and various. Table 14.1 represents an attempt at classification modified from Brain and Adams (1965) and remains useful today with a few additions (Grant 2002). Strict classification is impossible since the various disorders may appear singly or in combination. With the encephalopathies particularly, the pathological evidence suggests that a number of syndromes merge into one another as part of a spectrum. Of the syndromes in the table, only those likely to be of importance to the psychiatrist are considered in detail and these are summarised in Table 14.2 (Schott 2006).

With regard to prevalence, the non-metastatic complications are relatively uncommon and some varieties exceptionally so. Nevertheless, they constitute an important part of general hospital neurological practice. Among 1476 cases of carcinoma, Croft and Wilkinson (1965) obtained an overall prevalence of 7% with non-metastatic complications. Carcinoma of the lung produced by far the highest frequency at 16%. Hodgkin's disease and lymphoepithelioma of the

MRI temporal lobe signal change	57	83
Epileptic seizures	50	58
Primary tumour		
Lung	50	54
Testis	20	8
Breast	8	13

thymus have also been reported in association with such disorders.

Subacute cerebellar degeneration

This was one of the earlier syndromes to gain recognition (Brain *et al.* 1951) and in patients over 50 years old neoplastic origin is the cause of half of all subacute cerebellar degenerations (Bolla & Palmer 1997). The presenting symptom is

usually ataxia of gait, spreading later to all four limbs and often to the trunk. Dysarthria is severe but nystagmus often slight or absent. Muscle weakness, dysphagia, diplopia and sensory symptoms may also occur. The CSF is often abnormal with a pleocytosis, elevated immunoglobulins and oligoclonal bands. The diagnosis may sometimes be confirmed by the presence in serum and CSF of antibodies directed against cerebellar Purkinje cells (Clouston *et al.* 1992; Greenlee *et al.* 1992).

Mental symptoms figure prominently in the majority of cases. Most present with dementia but some also with agitation, anxiety and depression. The onset may antedate the appearance of the carcinoma by several months or years, or follow it by a similar interval. Once started the disorder may progress so rapidly that the patient is bedridden within weeks, while in other cases it may take a year to develop fully. Sometimes arrest may be seen after many months of progression, but remission does not occur. The dementia can continue to progress after the cerebellar affliction has stabilised. Treatment of the neoplasm has no demonstrable effect on the progress of the disorder.

The striking pathological change is the disappearance of Purkinje cells from the cerebellum. Diffuse degeneration is seen in other cerebellar neurones, and patchy microglial proliferation in the white matter of the cerebral and cerebellar hemispheres. In contrast, the dentate nuclei are often little affected. Degeneration may occur in the long tracts of the cord, especially the spinocerebellar tracts and posterior columns, and in the oculomotor and lower cranial nerve nuclei. Meningeal and perivascular lymphocytic infiltration is seen in some cases, and inflammatory changes have been observed in the brainstem and subthalamic region.

Rather similar to the above is opsoclonus, consisting of rapid chaotic conjugate eye movements that severely distort ocular fixation and which are often accompanied by ataxia. This can be abrupt in onset, in contrast to subacute cerebellar degeneration, and sometimes progresses to coma and death within several weeks. It may be associated with myoclonus and encephalopathy, but coordination of the individual limbs is preserved. A proportion of cases show a useful clinical response to treatment with corticosteroids, suggesting that the disorder may be due to immune reactions to tumour antigens affecting the brainstem neurones. Pathological changes involve loss of Purkinje cells and neuronal changes in the inferior olives, along with diffuse mononuclear infiltration of the brain parenchyma and leptomeninges. The disorder is characteristically seen with neuroblastoma in childhood, but also with tumours of the lung, breast and ovary in adults.

Encephalopathy with brainstem involvement

This, the so-called ‘mixed form of encephalomyelitis’ of Brain and Henson (1958), presents with varied neurological signs including cerebellar disorder, bulbar palsy, disordered

external ocular movements, wasting and weakness of the limbs, extensor plantar responses, involuntary movements and posterior column sensory disturbance. Mental changes are again prominent in many examples, including dementia. The disorder can follow a prolonged course over 2 years or more. In one case the neurological manifestations had been evident for 2 years before serial radiography revealed carcinoma of the lung.

The pathological changes involve degeneration in the dentate nucleus, superior cerebellar peduncles, brainstem nuclei, motor cells of the cord, and the pyramidal tracts and posterior columns. Inflammatory changes may be conspicuous, with perivascular cuffing and cellular infiltrations of the meninges.

Encephalopathies presumed due to metabolic disturbance

An important but apparently rare group of cases has been described in which marked mental disorders are associated with carcinoma of the lung yet cerebral changes prove to be minimal or absent on detailed pathological examination (Charatan & Brierley 1956). The common feature in such cases was a fluctuating disturbance of consciousness with periods of lucidity, extending over several months prior to death and unaccompanied by neurological abnormalities. Affective disturbances were often prominent in the earlier stages. In all cases the mental disturbance had either preceded or overshadowed the presence of the neoplasm. Here it would seem very likely that metabolic disturbances were fundamental to the development of the mental changes.

The first of Charatan and Brierley's cases was a man of 53 who became depressed and quarrelsome over several months. He later developed paranoid religious delusions and episodes of grossly muddled and odd behaviour. There were no organic features in the mental state and a diagnosis of paranoid schizophrenia was made. After recovering briefly for a week or two he abruptly relapsed, and at this stage carcinoma of the lung was detected. A quick decline led to coma and death.

The second was a man of 43 admitted after wandering from home in a depressed and apathetic state. He had lost his memory but this returned 4 days after admission. The only abnormal sign was some lability of mood. Soon, however, he developed periods of confusion with lucid intervals and deteriorated to death over 4 months. There had been suspicious shadowing of the lung for some months before presentation.

The third was a man of 63 who for 1 year had been slow, lethargic and complaining of feeling tired. Six months before presentation there had been an episode of confused nocturnal rambling, and since then his memory had been failing from time to time. Major epileptic fits had com-

menced at this time and chest radiography had shown shadowing of the lung. Gradual decline was accompanied by lucid intervals lasting a few days at a time. The mental state continued to show marked fluctuation in hospital until he died 2.5 months later.

Electroencephalography had shown little abnormality in the first two cases, and the CSF was normal except in the first. In all three the brain was free from metastases and only a marginal gliosis of the white matter could be detected. However, the livers contained numerous metastases and it was thought possible that liver failure may have contributed to the picture, either with or without other metabolic disturbances occasioned by the neoplasms.

Limbic encephalopathy and 'chemobrain'

Other patients present with mental disturbance in association with pathological changes largely limited to the limbic grey matter of the brain. The carcinoma is often bronchial in origin (small cell), often with metastases in the hilar lymph nodes but without direct spread to the brain, although primaries in testes and lymphomas have been described. In several examples the neoplasm has become evident only at post-mortem examination. Strangely, the primary growth has not always been discovered even then, the only evidence of cancer sometimes being secondary deposits in the mediastinal lymph nodes. Very occasional examples have also been reported with neoplasms of the bladder, mediastinum and thymus (Bakheit *et al.* 1990; Schott 2006).

This form of encephalopathy was comprehensively described by Corsellis *et al.* (1968). The outstanding clinical feature is a marked disturbance of memory for recent events, although some degree of generalised intellectual impairment often develops later. Affective disturbance is frequently prominent early in the evolution of the disorder, usually in the form of severe anxiety or depression. Some patients are hallucinated and some have epileptic attacks, but otherwise impairment of consciousness is not observed. Several patients have shown a coincident carcinomatous neuropathy.

The first report of such a picture in association with carcinoma was included among cases reported by Brierley *et al.* (1960), although the connection was not appreciated at the time. One of their patients with 'subacute encephalitis of later adult life' was a man of 58 who demented over the course of 3 months and died, revealing an intense inflammatory reaction in the brain, most severe in the medial temporal lobe structures. The mediastinal lymph nodes were extensively infiltrated with oat-cell carcinoma though neoplasia had not been suspected during life.

Bakheit *et al.* (1990) review the more recent literature on the condition. Symptoms had predated the diagnosis of malignancy in almost one-third of cases, and neurological findings

were few unless other brain regions were involved. CT was usually unhelpful in diagnosis, and MRI was normal in two of three cases examined and nowadays is often able to detect medial temporal lobe signal change with FLAIR sequences. EEG can also be normal or show non-specific abnormalities over the temporal lobes, in contrast to the distinctive picture seen with herpes encephalitis. The CSF is usually abnormal with a raised lymphocyte count and raised immunoglobulin level. Oligoclonal bands may be detected. The course in various cases has varied widely from a few weeks to up to 5 years.

The pathological picture shows a combination of degenerative and inflammatory changes that are concentrated on the medial temporal lobe structures: the hippocampus, uncus, amygdaloid nucleus, dentate gyrus, hippocampal gyrus, cingulate gyrus, insular cortex and posterior orbital cortex. The changes can sometimes extend throughout the length of the fornices and involve the mamillary bodies. The rest of the hemisphere and the hindbrain are only slightly affected. The changes consist of extensive neuronal loss, marked astrocytic proliferation and fibrous gliosis, and perivascular infiltration with small round cells and the formation of glial nodules. In no cases have tumour cells been identified within the CNS. The severity of the inflammatory component has varied from case to case, but at times has been severe enough to be virtually indistinguishable from viral encephalitis. No inclusion bodies have been seen. Bakheit *et al.* (1990) suggest that immune damage to the limbic neurones is a more plausible explanation than an infective aetiology and this has largely been confirmed (Schott 2006).

The most recent example of this group of disorders is one where antibodies to the NMDA receptor are produced. This has been described in a series of 12 young/middle-aged women who were found to have an ovarian teratoma (Dalmau *et al.* 2007) (Fig. 14.2). Removal of the primary tumour plus immunotherapy usually but not always cured the disorder. Many presented with florid psychopathology including psychotic or catatonic symptoms, 'acute personality change' or panic; most had seizures and generalised slowing on EEG. We have recently seen such a patient, a 21-year-old student with no previous history who became acutely depressed over 24–48 hours. Her overriding mood was of fear. She was mute and perplexed and was admitted initially to a psychiatry ward where her behaviour was extremely disturbed, with incontinence and faecal smearing. As she became more mute and withdrawn, encephalitis was suspected and confirmed by EEG. MRI was normal. Diagnosis was eventually made with the relevant immunological tests, although no underlying malignancy was identified, and the patient was treated with steroids and plasmapheresis. She made a gradual recovery after 2 months.

How commonly mental disturbance in patients with carcinoma may be due to limbic system involvement is hard to assess. As already described some examples are clearly due to more diffuse cerebral pathology or to metabolic disturbances, but where memory failure is a predominant feature the possibility of limbic encephalopathy should be borne in mind.

A wide variety of hypotheses have been proposed to explain the neuropsychiatric, non-metastatic complications of carcinomas. These have included toxins released from the cancer, defective immune system resulting in opportunistic viral infection or a direct effect of perturbation in immune function. Evidence to support an immune aetiology has grown over the last few years.

Also important to patients are the effects of therapy and the impact of disease. An extensive literature points to mild and possibly transient cognitive deficits associated with chemotherapy (Jansen *et al.* 2007; Nelson *et al.* 2007; Taillibert *et al.* 2007). Sometimes called 'chemobrain', a better term has been proposed: 'cancer- or cancer-therapy-associated cognitive change' (Hurria *et al.* 2007; Taillibert *et al.* 2007). Increasing attention is being paid to the long-term consequences as progress in oncology results in more patients living normal lifespans.

Normal-pressure hydrocephalus

Normal-pressure hydrocephalus is a syndrome of gait disturbance, cognitive impairment and urinary incontinence that may be secondary to other diseases such as traumatic brain injury or meningitis or primary, in which case it is known as idiopathic normal-pressure hydrocephalus (INPH) (Gallia *et al.* 2006). It owes its delineation to a group of workers who demonstrated cases in whom marked hydrocephalus was associated with normal or even low intraventricular pressure, sometimes after head injury or subarachnoid haemorrhage but sometimes in patients suspected of a primary dementing illness (Hakim 1964; Adams *et al.* 1965; Hakim & Adams 1965; Adams 1966). Air encephalography showed the absence of any block within the ventricular system, but the air failed to ascend over the surface of the hemispheres betokening obstruction within the basal cisterns or cerebral subarachnoid space. Paradoxically, despite the normal intraventricular pressure, the neurological and mental impairments sometimes proved to be reversible by shunting procedures that reduced the pressure still further.

Clinical features

The incidence of INPH has been estimated to lie between approximately 2 per 100 000 and 2 per 1 million population (Vanneste *et al.* 1992; Krauss & Halve 2004). It is essentially a disorder of the elderly.

The mental changes are a prominent part of the picture throughout. The appearance is of a subcortical dementia type syndrome, with inattention, psychomotor retardation and executive function difficulties (Gallia *et al.* 2006). Aphasia are uncommon. Forgetfulness is usually a prominent early feature, combined with slowing of mental and physical activity, difficulty with thinking and reduced spontaneity, a combination which may lead to a diagnosis of early presenile dementia or depression. Emotional reactions are less vivid

Fig. 14.2 Brain MRI findings in three patients with *N*-methyl-D-aspartate receptor encephalitis associated with ovarian teratoma (Dalmau *et al.* 2007). (a, b) Patient 1 at symptom presentation (a) and after partial clinical improvement and CSF normalisation with immunotherapy (b). (c, d) Patient 2 at symptom presentation (c) and 4 months later (d); this patient developed rapidly progressive neurological deterioration that did not respond to immunotherapy. (e, f) Patient 3 at symptom presentation; note the mild fluid-attenuated inversion recovery hyperintensity in medial temporal lobes and right frontal cortex. After immunotherapy and tumor resection, the MRI was normal (not shown).

and psychic life seems generally impoverished. Insight is limited or absent from an early stage but social comportment is usually well preserved.

Disturbance of gait may be the presenting feature. In mild examples the patient walks slowly on a broad base with a stiff-legged shuffling gait. There is difficulty with turning and often difficulty with initiating movements similar to that seen in parkinsonism. Falls are frequent. The precise nature of the disturbance is hard to characterise but is often described as an uncertainty, unsteadiness or carelessness in walking. The ill-defined term 'gait apraxia' has been applied. When coupled with the mental symptoms, this abnormality of gait is often the feature which leads one to suspect the presence of normal-pressure hydrocephalus. The disturbance may progress eventually to severe difficulty in walking, standing or arising from a seated position, sometimes even to difficulty in turning over in bed. Signs of spastic paraparesis may be evident with hyperactive tendon reflexes and extensor plantar responses. However, even when the disability is pronounced it is rare to find frank ataxia of the limbs, dysynergia or intention tremor of cerebellar type.

Urinary incontinence usually appears only when other symptoms are evident, but may set in surprisingly early in relation to the degree of mental impairment. Again this may have diagnostic importance in bringing the condition to mind. Bladder hyperactivity can be demonstrated on urodynamic testing (Ahlberg *et al.* 1988). Faecal incontinence is rare and develops only in the most severe examples.

Other features may include slowness of movement in the upper limbs or occasionally some degree of arm tremor or ataxia. Unexplained nystagmus is occasionally present. Late in the course sucking and grasping reflexes may appear. Headache is rare and when present is usually minimal. Papilloedema does not develop. A history of falling spells with brief impairment of consciousness is common, but frank epileptic seizures have not been reported.

The course without treatment is of slow downward progression with increasing neurological and mental disability. Fluctuations from day to day or from week to week are very characteristic. In some of the more prolonged examples a plateau appears to be reached after many months with a relatively fixed pattern of impairments thereafter. Others progress eventually to coma and death.

Investigations

The findings on investigation are characteristic and necessary to confirm the diagnosis (Relkin *et al.* 2005). These include CSF flow analyses and neuroimaging. EEG is frequently abnormal, showing non-specific random theta or delta activity.

Imaging is an essential part of the diagnostic process. Before the advent of CT, air encephalography usually provided the decisive evidence by way of symmetrically

enlarged ventricles, often reaching huge proportions, but with little or no air in the cerebral subarachnoid space above the basal cisterns. Following the procedure, however, there was a risk of rapid deterioration, sometimes requiring urgent neurosurgical intervention.

Structural imaging with CT or MRI demonstrates the enlarged ventricles. Other findings may include periventricular hyperintensities, thinning of the corpus callosum and no evidence of obstruction to CSF flow (Relkin *et al.* 2005). MRI finds a special place in the detection of minor obstructive lesions that might otherwise be missed, particularly in the posterior fossa.

Tests of CSF dynamics include the CSF tap test, external CSF drainage and CSF outflow resistance determination. Although there are no definitive diagnostic tests, the judicious use of CSF analyses can increase predictive accuracy to 90% (Marmarou *et al.* 2005). The CSF tap test involves the withdrawal of large volumes (40–50 mL) of CSF and then careful monitoring of symptoms. Improvement suggests, with high accuracy, a good response to intervention is likely but the test has low sensitivity. The test can in effect be extended by external CSF drainage by an indwelling catheter and this gives good sensitivity and specificity but at some cost, as patients must be admitted to hospital and side effects including infection and nerve root irritation are higher than for other investigations. More commonly used is outflow resistance measurement: abnormally high values are associated with an improved response to therapy.

Secondary normal-pressure hydrocephalus

In many examples no antecedent cause can be discovered. In others there is a history of subarachnoid haemorrhage, head injury or meningitis which has presumably led to the organisation of adhesions in the basal cisterns of the brain. After subarachnoid haemorrhage, organisation of exudate within the arachnoid villi at the superior sagittal sinus may contribute further by obstructing the reabsorption of CSF. Very occasionally the typical clinical syndrome may be due to a partially non-communicating hydrocephalus occasioned, for example, by a third ventricular tumour or aqueduct stenosis. A rare cause has been described by Brieg *et al.* (1967) and Ekblom *et al.* (1969): in hypertensive individuals an elongated 'ectatic' basilar artery may indent the floor of the third ventricle and distort the ventricular system upwards and anteriorly, leading to normal-pressure hydrocephalus.

In Ojemann's (1971) material of 50 cases no cause could be found in 18. These 'idiopathic' cases were all in their sixties or seventies. Of the 32 with known causes, 12 followed subarachnoid haemorrhage, 11 head injury and three meningitis. Five were due to tumours or the after-effects of posterior fossa surgery and one was due to aqueduct stenosis. The age range in this group was wider, from 26 to 69 years.

Differential diagnosis

All three core symptoms – urinary incontinence, falls and ataxia and cognitive decline – are common in the elderly. The most important differential diagnosis is from the primary dementias. INPH should be suspected if early in the decline there appears a disorder of gait together with inertia, apathy and psychomotor retardation. Urinary incontinence developing before the mental impairments have proceeded very far should also raise suspicion.

A depressive illness may be simulated early in the course, when physical and mental slowness are prominent and intellectual impairment minimal. Several patients reported by Pujol *et al.* (1989) met *Diagnostic and Statistical Manual of Mental Disorders* (DSM)-III criteria for major depression. Rice and Gendelman (1973) drew attention to other ways in which the patient may first present to a psychiatrist. In five patients behavioural abnormalities were in the forefront of the picture, sometimes tending to obscure the organic features in the mental state. Examples included personality change with paranoid trends or increasing belligerence, acute agitation and paranoia accompanied by visual hallucinations, and marked anxiety and depression accompanying progressive dementia. In each case the hydrocephalus appeared to have aggravated pre-existing emotional difficulties in the patient in addition to producing intellectual impairment.

When the gait disturbance is the presenting feature, differentiation is required from other causes of mild spasticity and ataxia such as cervical spondylosis. Other differential diagnoses for the gait disturbance include arthritis and peripheral neuropathy. Parkinsonism may be suspected initially on account of the pronounced motor slowing. Some of the problems encountered in diagnosis are illustrated in the following cases.

A woman of 66 had had a radical mastectomy for cancer of the breast followed 1 month later by progressive unsteadiness of gait, forgetfulness and intermittent confusion. Within 6 months the memory disorder was pronounced and psychometry showed widespread impairments. There was no evidence of secondary deposits. The CSF was normal but air encephalography showed gross dilatation of the ventricles with no air over the cortical surface. She worsened precipitately after air encephalography and became drowsy, confused and almost mute. She could no longer walk and nystagmus was present in all directions of gaze. The CSF now showed what were thought to be neoplastic cells and a diagnosis of carcinomatous meningeal infiltration was made.

Over the next 15 months she did not deteriorate as expected. She gradually became more alert, though she

continued to speak little and took little notice of what went on around her. She lay or sat immobile, idle or watching television. On readmission she was grossly disorientated and with marked memory impairments, and showed no initiative whatsoever. She was incontinent of urine and faeces and could not sit or stand unsupported. The ankle reflexes were brisk and the plantars upgoing but there were no cerebellar signs. The syndrome of normal-pressure hydrocephalus was recognised and a shunt operation performed. Improvement was evident within 3 days and after 7 weeks her mental state had returned to normal. Control of bowel and bladder was regained, and when seen 9 months later she was walking by herself though still with an uncertain gait (Adams *et al.* 1965).

A man of 49 complained of lethargy, easy fatigability and vague weakness of the legs. For 6 months his family had noted him to be dull and forgetful. He was found to be slow in motor and verbal responses and with a mild impairment of recent memory. The plantar responses were extensor but there were no other abnormal neurological signs. CSF pressure was mildly elevated with a protein of 100 mg/dL. Air encephalography showed symmetrical dilatation of the ventricles with a small amount of air over the surface. A tentative diagnosis of Alzheimer's disease was made. In hospital there was considerable improvement in his apathy and inertia but he relapsed after a few weeks at home. Walking became seriously impaired, with a stiff-legged gait and several falls. On readmission he was now severely amnesic for recent events and disorientated in time and place. He improved again in hospital but the diagnosis of Alzheimer's disease remained.

Over the next 2 months he gradually declined into severe confusion and was readmitted pending transfer to a long-stay psychiatric hospital. He was now unkempt, apathetic and unconcerned, with great slowness on mental tasks. He walked with a wide-based stiff-legged gait and stumbled on turning. Bilateral grasp reflexes were observed, and a prehensile sucking reflex when the lips were touched. The Wechsler Adult Intelligence Scale (WAIS) IQ was 64, whereas 4 months earlier it had been 101. After lumbar puncture he changed remarkably, becoming alert and quick of mind, fully orientated and able to learn new facts, and the WAIS IQ rose to 105. Gait returned to normal but the plantars remained extensor. A shunt operation was performed with excellent results, and a small mass situated on the floor of the third ventricle encroaching on the entrance to the aqueduct was irradiated. Six months later he was back at his usual clerical job (McHugh 1966).

Treatment and response

Treatment involves a shunt operation to lower CSF pressure within the ventricles and maintain it at this low level. An indwelling catheter is inserted into a lateral ventricle, incorporating a low-pressure one-way valve, and opening either into the superior vena cava through the jugular venous system (ventriculocaval shunt) or into the peritoneal cavity (ventriculoperitoneal shunt). The latter are more commonly used. The result, though somewhat unpredictable, is gratifyingly successful in certain cases. Those patients who on intracranial pressure monitoring have shown elevated mean pressures or marked spontaneous pressure waves tend to show the best response (Jeffreys & Wood 1978; Crockard *et al.* 1980).

A wide range of shunts and catheters are available. Adjustable valves with subcutaneous controllers are increasingly used. These can be manipulated by the physician, allowing finer control of CSF pressure and avoiding over- and under-drainage. As the devices are magnetically controlled, this can result in problems for patients near magnetic sources, including MRI scanners (Gallia *et al.* 2006).

Shunt operations, even when dramatically successful initially, are not without their long-term complications (Jeffreys 1993). The catheter may become blocked or infected or shift its position, or the valve may cease to function. Over-drainage can result in headache, lethargy, strabismus, nausea and vomiting, typically relieved by lying down. The 'slit ventricle syndrome', commoner in those who have been shunted since early childhood, presents with a history indicative of intermittent obstruction and is probably also largely a consequence of previous over-drainage (Hendrick 1993).

Among INPH cases, Ojemann (1971) found satisfactory improvement after shunting in all patients where a complete block in the subarachnoid space had been demonstrated. The patients with only partial obstruction showed disappointing results, perhaps because some had a primary dementing illness in addition to their normal-pressure hydrocephalus. Pickard (1982) suggests that complete recovery can be expected in about one-third of patients, with useful improvement in a further 30%.

The improvement is often manifest immediately on recovery from the anaesthetic, with further gains in the days that follow. Sometimes, however, there is little change during the first postoperative week, gradual improvement then taking place over the next several weeks. The neurological deficits are usually the first to resolve, although gait disturbance sometimes responds only gradually. Incontinence typically clears fairly promptly. Intellectual deficits tend to improve more slowly, sometimes with maximal gains after several months. In favourable cases intellectual impairments, asponaneity and apathy can ultimately clear completely. Follow-up with repeat evaluation of cognitive

function has shown gains more obvious at 1 year than at 6 months, and well maintained thereafter (Crockard *et al.* 1980).

In secondary normal-pressure hydrocephalus following subarachnoid haemorrhage, improvement is likely within a few days of shunting but focal neurological deficits related to the local effects of the haemorrhage will often persist unaltered. The response in cases following head injury is governed by the degree and severity of the underlying brain damage. Salmon (1971) reported nine post-traumatic cases, operated at intervals of 6 months to 8 years after injury. Two were 'much improved' and three 'improved', including two patients who showed some evidence of cortical atrophy as well. The improvements often took place slowly over the course of several weeks.

Other forms of hydrocephalus

The best-known form of hydrocephalus is that which declares itself in infancy, resulting from obstruction along the course of the CSF pathways. This is usually due to developmental defects of the brain, haemorrhage following birth trauma, or an attack of meningitis. When the disturbance is manifest before the cranial sutures have closed there is progressive enlargement of the head. Usual accompaniments are varying degrees of spasticity, mental retardation and sometimes blindness, depending on the severity of the obstruction and the presence or absence of associated developmental brain defects. In some patients the hydrocephalus becomes arrested and intellect may occasionally be surprisingly well preserved. In cases due to developmental defects there are often other congenital abnormalities, particularly spina bifida and meningomyelocele. In adults obstructive hydrocephalus is mainly the result of new pathology, such as a tumour strategically situated to impede the CSF circulation within the brain. It commonly presents with symptoms of raised intracranial pressure but sometimes the initial picture can be misleading.

Occasionally, moreover, adult obstructive hydrocephalus is attributable to congenital defects or pathology acquired much earlier in life; a partial balance is then achieved between the production and absorption of CSF. Developmental defects such as aqueduct stenosis or partial obliteration of the foramina of the fourth ventricle can remain latent in this way. Headache is usual but not inevitable, and a spectrum is likely to exist between the cases considered here and those already described under the heading of normal-pressure hydrocephalus. A frequent feature is a history of attacks of abrupt loss of consciousness, lasting a few minutes during which the patient lies motionless and flaccid. Such attacks are often preceded or followed by headache and are presumably due to sudden rises of intracranial pressure. The mental changes, which may or may not accompany the neurological developments, can take the

form of listlessness, apathy and inattentiveness, progressing to a picture of dementia and inertia resembling frontal lobe disorder.

Aqueduct stenosis, in particular, may fail to declare itself until adolescence or mid-adulthood. Asymptomatic cases have also been found at post-mortem. The stenosis is usually the result of congenital defect, although some can be traced to an episode of meningitis in childhood and others show gliosis of unknown cause. Sometimes a small mass, such as a periaqueductal glioma, compresses the aqueduct from without. Symptoms of raised intracranial pressure may occur, sometimes following an intermittent crescendo pattern succeeded by periods of unconsciousness, but in others such evidence is completely lacking. Some present with unsteadiness of gait or with epilepsy, usually of psychomotor type. Others show hypothalamic symptoms such as impotence, amenorrhoea or obesity, due to pressure of the distended third ventricle on the pituitary and hypothalamus. Mental symptoms may be the presenting feature, with impairment of memory or generalised dementia. Of the 10 cases reported by Nag and Falconer (1966) only five presented with symptoms indicative of raised intracranial pressure, while memory disorder was the initial manifestation in four. Harrison *et al.* (1974) obtained a history of deterioration of memory and concentration in one-third of their cases. This was usually mild, but in two cases was sufficiently marked to be the feature that brought the patient to medical attention.

A man of 52 showed slow progression of gait disturbance and impotence following the death of his mother to whom he was closely attached. Six years later he was hospitalised and the disorder was ascribed to 'nerves'. Thereafter he developed emotional lability, mild memory impairment and occasional urinary incontinence. One year later mental testing was within normal limits except for moderate slowing of responses, but his gait was strikingly abnormal with tiny shuffling steps and difficulty in initiating movement. The CSF was normal and under normal pressure. Air encephalography showed aqueduct stenosis. Ventriculography showed dilatation of the lateral and third ventricles, and also of the upper 1 cm of the aqueduct. A shunt operation led to excellent resolution of his symptoms. He had had meningitis at the age of 5 and had complained frequently of headache throughout adult life (Wilkinson *et al.* 1966).

An example reported by Ojemann *et al.* (1969) is also instructive:

A woman of 54 had an 18-month history of progressive change of personality and failure of mental functions. She became disinterested in people and activities, and showed inattentiveness and difficulty with calculation. Some months later her gait became unsteady and her left hand tremulous, leading to a diagnosis of parkinsonism. Deterioration progressed relentlessly with marked apathy and incontinence of urine. On examination she showed impairment of memory and other intellectual functions, a slight left hemiparesis and spasticity in the legs. On sitting down she took 30 seconds to complete the last 4 inches, and on approaching a step she raised her foot too early and too high. CSF pressure was normal, and air encephalography showed air in the fourth ventricle but none in the aqueduct. Ventriculography displayed large lateral and third ventricles, with gross dilatation of the rostral part of the aqueduct and a nodular mass projecting from the region of the quadrigeminal plate. A shunt operation produced striking improvement and she was entirely normal 1 year after operation.

An interesting association of aqueduct stenosis has been reported by Reveley and Reveley (1983). In the course of examining the CT scans of schizophrenic patients they found three with aqueduct stenosis. Two were known to be hydrocephalic from shortly after birth, while in the third the condition was entirely unsuspected. The significance of this association remains at present unclear.

The diagnosis rests ultimately on radiographic studies along with CT or MRI. Erosion of the dorsum sellae is shown on plain radiography in the majority, and the lateral and third ventricles are seen to be symmetrically enlarged. The aqueduct is either not displayed or is seen to be very narrow. Intraventricular pressure may be elevated or normal.

Shunt operations can be dramatically successful in relieving the symptoms whether or not the pressure has been raised. However, a considerable failure rate is seen mainly due to obstruction within the subarachnoid space (McMillan & Williams 1977).

Other disorders affecting the CNS

Progressive multifocal leucoencephalopathy

This rare disorder is an uncommon complication of chronic disorders with compromised immune function, most notably HIV/AIDS in recent years (Wyen *et al.* 2005; Berger 2007; Drake *et al.* 2007). Other chronic diseases where progressive multifocal leucoencephalopathy (PML) may be a complication include lymphoma, Hodgkin's disease, leukaemia or sarcoidosis. The disorder results from oppor-

tunistic infection of the brain by JC polyomavirus (Khalili & White 2006).

A very few patients receiving natalizumab for MS or Crohn's disease, especially if also being treated with immunosuppressive agents, succumbed to PML (Gold *et al.* 2007). Most affected patients have been between 30 and 60 years of age. Progressive dementia is accompanied by neurological manifestations indicative of focal involvement of the CNS: pareses, ataxia, dysphasia and visual field defects. Rapid mental and neurological deterioration typically leads to death within a few weeks or months, but very occasional cases have shown slow progression over several years. MRI features include hyperintense lesions in periventricular and subcortical white matter most often in parieto-occipital or frontal lobes, but also elsewhere in the brain (Whiteman *et al.* 1993). MRI is more sensitive than CT which shows low-density lesions in the central and convolutional white matter, often with a distinctive 'scalloped' appearance to their lateral borders (Carroll *et al.* 1977). Such lesions do not enhance, and are without mass effect. Despite these changes, diagnosis is complicated and may require biopsy (Pelosini *et al.* 2008), especially since the virus often cannot be detected in CSF in patients treated with antiviral drugs (Koralnik 2004).

At post-mortem, scattered crumbling foci of softening are seen as small round greyish areas throughout the brain. They are situated mainly in the white matter, affecting the cerebral hemispheres, cerebellum and brainstem, and showing a special predilection for the junction of cortex and subcortex. Within such areas there is marked demyelination along with relative preservation of the axis cylinders. Perivascular lymphocytic cuffing is usually well developed. A unique stamp is given by the changes observed in the glial cells. Astrocytes are enormously enlarged, with bizarre distorted nuclei that often show abnormal mitoses. The oligodendroglial nuclei often contain inclusion bodies.

The availability of highly active antiretroviral therapy (HAART) has improved the prognosis of PML in HIV/AIDS: 3-month mortality has decreased from 90% to 50% (Koralnik 2004). However, the incidence remains unaffected as does prognosis when PML occurs in the context of other diseases.

Adrenoleucodystrophy

This group of disorders includes neonatal and childhood adrenoleucodystrophy, Zellweger's cerebrohepato-renal syndrome and adult-onset adrenomyeloneuropathy. The biochemical abnormality they share is the accumulation of very-long-chain saturated fatty acids (VLCFA), particularly hexacosanoate, in lipid-containing tissues including the brain. Characteristic lamellar inclusions can be shown in the Schwann cells of the nervous system and the cells of the adrenal cortex. The diagnosis may be made by demonstrating increase in VLCFA (Moser *et al.* 1999) or ultrastructural examination of nerve terminals biopsied from the skin or

conjunctiva. The childhood and adult-onset forms are both sex-linked, appearing only in males, and may be found in the same family. MRI lesions are seen in both adult and childhood-onset forms but progress slower in the adult form (Eichler *et al.* 2007). The defect in these X-linked cases is in the *ABCD1* gene, where over 500 separate mutations have been shown to cause disease (Moser *et al.* 2004). The gene encodes a protein that has a role in peroxisomal β -oxidation and hence fatty acid metabolism.

Childhood cerebral adrenoleucodystrophy often presents with inattention, hyperactivity and emotional lability. Visual, auditory and motor symptoms follow and the course of the condition is then very rapid. However, mutations in the *ABCD1* gene in the absence of overt cerebral involvement do not result in an altered IQ (Cox *et al.* 2006). Adrenal insufficiency may not be apparent at the time of presentation but Addison's disease develops eventually. Occasionally this precedes the nervous system involvement.

The neonatal form of infantile adrenoleucodystrophy, Refsum disease and Zellweger's syndrome are all overlapping peroxisome biogenesis disorders caused by mutations in one of the many peroxin genes. As in other adrenoleucodystrophy disorders, VLCFAs accumulate because of the defect in lipid peroxidation. A severe neonatal disorder is the consequence, with facial malformation, renal and hepatic abnormality, death usually before the age of 5 years and histological evidence of leucodystrophic change in the brain.

Adrenomyeloneuropathy presents with spastic paraparesis and sensory loss in the legs due to peripheral nerve involvement, proceeding sometimes to dementia. In rare examples the presentation has been with focal cerebral deficits, Klüver-Bucy syndrome, dementia resembling Alzheimer's disease or spinocerebellar degeneration (Moser *et al.* 1984).

Adrenoleucodystrophy came to the attention of the public with the film *Lorenzo's Oil*. This highly controversial film was reviewed by Moser, a leading clinician and researcher in the field who identified himself as possibly one of the characters in the film (Moser 1993). The film tells the fictional story of a boy affected by the disease and his family's search for a cure. Whether 'Lorenzo's oil' (4:1 glyceryl trioleate-glyceryl trierucate) is efficacious is nearly as controversial as the film. It appears to lower VLCFA and to delay progression of MRI lesions (Moser *et al.* 2005) but clinical benefits have not been demonstrated (Aubourg *et al.* 1993).

Dementia with familial calcification of the basal ganglia (adult-onset bilateral striopallidodentate calcinosis, Fahr's syndrome)

Basal ganglia calcification is, in itself, a benign finding on neuroimaging, with no increase in dementia (Forstl *et al.* 1992). However, in the syndrome of adult-onset bilateral striopallidodentate calcinosis in the absence of calcium or

parathyroid hormone imbalance, dementia is a feature. Reports in the literature have included both apparently sporadic cases and those inherited in an autosomal dominant fashion. The largest series comprised 38 patients from five autosomal dominant families and eight isolated individuals (Manyam *et al.* 2001). Cognitive symptoms were the most frequent after motor effects.

Many affected persons are asymptomatic for long periods of time, although it seems likely that most eventually show some form of extrapyramidal dysfunction. Parkinsonism or choreoathetosis usually develop in late middle age, or more rarely cerebellar ataxia or pyramidal deficits. Progressive impairment of memory and intellect frequently accompany the motor manifestations, with slowing of cognitive processes typical of subcortical dementia. Dysphasia and other focal cortical deficits are not observed. In several cases a psychosis indistinguishable from schizophrenia has been reported, often antedating the motor and cognitive manifestations by many years. Francis (1979) and Francis and Freeman (1984) have reported nine patients in four generations of a family in whom a schizophrenia-like psychosis appeared to be the principal accompaniment of the disorder.

Cummings *et al.* (1983) review the literature on the condition, finding indications of two relatively distinct patterns of presentation. Those who present with psychotic episodes tend to do so in their early thirties, those with dementia and motor disorder some 20 years later. Both share the characteristic finding of dense calcification symmetrically involving the basal ganglia and particularly the putamen. The dentate nuclei of the cerebellum and the pulvinar of the thalamus may also be heavily affected.

Other conditions leading to calcification within the basal ganglia must be excluded, the commonest being hypoparathyroidism and pseudohypoparathyroidism. Hyperparathyroidism may occasionally produce a not dissimilar radiological appearance. Investigation of serum calcium and phosphate serves to make the distinction since these have uniformly proved to be normal. Other causes of calcification such as toxoplasmosis, tuberous sclerosis or the sequelae of encephalitis or anoxia will also need consideration when the familial nature of the condition is not apparent.

In a review of the literature, Flint and Goldstein (1992) cast doubt on the syndrome as an independent clinical entity, suggesting that at least some cases are variants of pseudohypoparathyroidism. Some of the associated features of the latter, such as short stature and shortened metacarpals, occurred in their own familial cases and in other reported examples. Flint and Goldstein also conclude that schizophrenia, when carefully delineated, is uncommon and may represent no more than a chance association.

A locus on chromosome 14 was linked to one very large family that had decreasing age of onset in each generation, suggesting the phenomenon of anticipation (Geschwind

et al. 1999). Subsequently some, but not all, families with the condition were shown to have linkage to the same region, demonstrating that this is a heterogeneous condition (Oliveira *et al.* 2004). Interestingly, in one family where probands had basal ganglia calcification, dementia, bipolar affective disorder and parkinsonism, prompting a diagnosis of Fahr's syndrome, the neuropsychiatric symptoms were found to be independent of basal ganglia calcification and linkage to the locus on chromosome 14 was excluded (Brodaty *et al.* 2002).

Neurodegeneration with brain iron accumulation (pantothenate kinase-associated neurodegeneration, Hallervorden–Spatz syndrome)

A heterogeneous group of related disorders result from deposition or accumulation of iron in the basal ganglia. Described first in 1922 by Hallervorden and Spatz in a family with dementia and dysarthria, the condition presents classically in the first decade of life with death before the age of 30 years, although atypical presentations can be later. Dooling *et al.* (1974) describe the typical features of early onset of a motor disorder mainly of extrapyramidal type, the mental changes of dementia, and a relentlessly progressive course leading to death on average 11 years later. Of their 42 examples from the literature, mental changes had been the first manifestations in four. In more than half the onset had been before the age of 10, but one had begun at 30 and two others at 57 and 64 years. The disorder is inherited as an autosomal recessive disease. The late-onset cases were non-familial and died after 5–6 years.

Motor abnormalities consist mainly of rigidity, dystonia and choreoathetoid movements, although spasticity and pyramidal signs may appear. Dysarthria is almost always present and facial grimacing may occur. Myoclonus and tremor are not uncommon. Abnormalities of posture or movement are the usual presenting symptoms, often interfering with walking. Vision may be impaired due to retinopathy or optic atrophy.

A change of personality sometimes sets in early, with depression and outbursts of aggressive behaviour. Intellectual deterioration then gradually develops along with the motor manifestations, often progressing to mutism in the terminal stages.

There are no abnormal findings in the blood or CSF. EEG shows slowing as the disease advances, sometimes with spikes and sharp waves. The CT scan may resemble that seen in Huntington's chorea, with prominent atrophy of the basal ganglia (Dooling *et al.* 1980). Generalised atrophy of the cortex, brainstem and cerebellum may also be apparent. MRI shows destruction of the central part of the globus pallidus, surrounded by dark signal due to iron deposition ("eye of the tiger" sign) (Angelini *et al.* 1992).

At post-mortem the distinctive finding is reddish-brown discoloration of the globus pallidus and pars reticulata of the substantia nigra, due to the accumulation of iron-containing pigment. Microscopy shows loss of neurones in the affected areas with demyelination and gliosis, and numerous oval or rounded structures (spheroids) which are identifiable as axonal swellings. The latter are frequently widely disseminated in the cortex, although this may otherwise show little by way of neuronal loss or gliosis. The Purkinje cells of the cerebellum may be depleted.

Neurodegeneration with brain iron accumulation (NBIA) is found in two variants, type 1 and type 2. NBIA1 is caused by mutations in the *PANK2* gene (Zhou *et al.* 2001) and NBIA2 by mutations in the *PLA2G6* gene. *PANK2* codes for a pantothenate kinase involved in coenzyme synthesis from vitamin B₅ (pantothenic acid). Loss of the gene in mouse results in a retinopathy (Kuo *et al.* 2005). A variety of similar syndromes to NBIA1 have been reported. One example, also known as Karak syndrome, was found to have mutations in the *PLA2G6* gene coding for a phospholipase (Mubaidin *et al.* 2003; Morgan *et al.* 2006). The heterogeneity and complexity of these syndromes is illustrated by the fact that a mutation in *PLA2G6* also causes infantile neuroaxonal dystrophy (Khateeb *et al.* 2006) and mutations in *PANK2* also cause the closely related HARP syndrome (hypoprebetalipoproteinaemia, acanthocytosis, retinitis pigmentosa, and pallidal degeneration) (Ching *et al.* 2002).

The names of Julius Hallervorden and Hugo Spatz are notorious as participants in one of medicine's more shameful episodes. Hallervorden, who replaced Max Bielschowsky as head of neuropathology in Berlin when Bielschowsky was dismissed from his post as a Jew, and Spatz, who once worked in Kraepelin's department with Nissl, were Nazi war criminals and the recipients of brain material from the 'euthanasia', or murder, of mentally ill children and adults (<http://www.whonamedit.com>).

Neuroacanthocytosis (choreoacanthocytosis)

Neuroacanthocytosis is a rare syndrome of progressive neurodegeneration and acanthocytosis most familiar in the autosomal recessive form known as choreoacanthocytosis but also occurring in abetalipoproteinaemia and X-linked McLeod syndrome (Rubio *et al.* 1997). Acanthocytes are abnormal red blood cells, detected in fresh blood films by their spiny protuberances. They must be carefully distinguished from echinocytes, which show a not dissimilar appearance, and from other artefactual changes in red cell morphology (Hardie 1989). Acanthocytes are also found in abetalipoproteinaemia (Bassen-Kornzweig syndrome), a condition usually appearing in the first decade of life and accompanied by fat malabsorption, spinocerebellar ataxia and pigmentary retinopathy. These features are attributed to defective absorption of vitamin E. In neuroacanthocytosis,

however, lipid metabolism is entirely normal. The locus for choreoacanthocytosis has been clearly identified on chromosome 9p21 (Rubio *et al.* 1997) with a novel gene *CHAC* or *VPS13A*, coding for the protein chorein, being the most likely culprit (Rampoldi *et al.* 2001; Dobson-Stone *et al.* 2002; Ruiz-Sandoval *et al.* 2007).

The condition usually comes to attention in early middle age, although the range of onset is wide. Involuntary movements, chiefly choreic, are accompanied by hyporeflexia or areflexia and sometimes by muscle wasting. Seizures occur in perhaps half of cases. Steady and slow progression of deficits is the rule over several decades, though there is much variability. Hardie *et al.* (1991) presented 19 cases with a review of the relevant literature. Movement disorder is virtually universal, with choreiform and dystonic movements affecting the orofacial region and sometimes the limbs. In severe examples there may be biting of the tongue and lips, also pseudobulbar features with difficulty with speech and swallowing. Tongue protrusions and severe grimacing may occur. Tics can also be prominent, along with grunting, sniffing and spitting. Vocalisations sometimes develop, usually of monosyllabic words. A peculiar lurching gait may be seen, with dipping of the knees and foot flap. A minority of cases progress to an akinetic-rigid state. Muscle wasting and weakness can affect distal or proximal groups, hyporeflexia being common even in its absence.

Among psychiatric features depression, anxiety and obsessive-compulsive disorder are not infrequent. Hardie *et al.* (1991) also report a characteristic organic personality change, leading to vagueness, distractibility and neglect of appearance and social skills. In fact the literature is scattered with examples of misdiagnosis emphasising pleiotropy of the condition (Walker *et al.* 2007). Examples of neuroacanthocytosis presenting for example as Huntington's disease (Gold *et al.* 2006), schizophrenia and Tourette's syndrome (Bruneau *et al.* 2003; Muller-Vahl *et al.* 2007) are reported. Dementia has been clinically evident in some half of reported cases, but neuropsychological evaluation may show deficits in many more, particularly on tests of attention and planning indicative of frontal lobe disorder. Investigation in suspected cases must include a careful search for acanthocytes in fresh blood films, repeated if necessary on several occasions since the abnormal cells can be relatively rare in the early stages. The serum creatinine kinase may or may not be elevated. CT often shows caudate atrophy, or generalised cerebral atrophy in the presence of dementia. MRI may show increased T2 signals from the basal ganglia. At post-mortem there is extensive neuronal loss and gliosis in the corpus striatum and globus pallidus, also sometimes in the lateral substantia nigra. The caudate nucleus may be virtually depleted of both large and small neurones. The hemisphere white matter shows mild diffuse gliosis, but the cortex itself is spared.

Differential diagnosis must obviously include Huntington's disease, especially in patients who show a

dominant pattern of inheritance. The presence of seizures, muscle wasting, areflexia or evidence of neuropathy should immediately raise suspicion of neuroacanthocytosis, also good preservation of cognitive function late into the disease. Gilles de la Tourette's syndrome may sometimes be closely simulated, likewise tardive dyskinesia if the patient has been on neuroleptic medication. Estimation of serum lipids will reveal those patients whose acanthocytosis is due to abetalipoproteinaemia.

Metachromatic leucodystrophy

This rare cause of dementia and motor disorder is inherited in an autosomal recessive fashion due to mutation in the arylsulphatase A gene (*ARSA*). The two most common mutations in the population occur with a frequency of 13–17% (Barth *et al.* 1994) and have been reported to also occur more often than expected in vascular dementia (Philpot *et al.* 1997). Metachromatic leucodystrophy represents an abnormality of neural lipid metabolism, with accumulation of galactosyl sulphatide in affected tissues. Deposits of the material stain metachromatically. Kihara (1982) describes five allelic variants: late infantile, juvenile, and adult forms, partial cerebroside sulphate deficiency, and pseudoarylsulphatase A deficiency. The infantile form represents the classic disease, setting in before the age of 3 and progressing to severe motor and mental retardation, sometimes with blindness. The juvenile form is less common, presenting with motor and mental dysfunction and sometimes resembling a spinocerebellar disorder.

The adult form is rarest of all. Onset in recorded cases has varied from 19 to 46 years, presenting sometimes with dementia and sometimes with psychotic disorder. Motor dysfunction is less prominent and may develop only later in the disease. In adults the course can be extremely protracted over several decades; mistakes in diagnosis are common and unless a sibling has already been affected, the condition may go unsuspected during life. Common misdiagnoses include early-onset dementia, schizophrenia or multiple sclerosis.

Cummings and Benson (1992) refer to reports of the condition first diagnosed as schizophrenia or presenting with expansive delusions suggestive of mania. When motor abnormalities eventually appear, they take the form of pyramidal and extrapyramidal dysfunction with paresis, dystonic movements, dysarthria and parkinsonism. Ataxia, nystagmus and intention tremor are common. Seizures often occur, and peripheral neuropathy is usually present.

Hyde *et al.* (1992) have drawn attention to the special liability of adolescent and early adult cases to present with psychotic disorder, this appearing to be restricted to such an age of onset. Thus of 129 published case reports, 55 patients had had an onset between the ages of 10 and 30 years, and 29 of these (53%) showed psychotic symptoms. This was the most frequent presenting feature in the age group concerned, and

seemed considerably more common than with other neurological disorders. No such symptoms were apparent in the 74 cases with juvenile or later adult onset. Typical symptoms included auditory hallucinations, sometimes of voices commenting on the patient's behaviour, complex delusions, fragmentation of thinking, inappropriate affect, bizarre behaviour or catatonic posturing. Many of the psychoses appeared at first to be non-organic, and 15 patients had been diagnosed as suffering from schizophrenia. Two showed mania and three personality change. The false diagnoses sometimes persisted for several years before dysarthria, spasticity and hyperreflexia appeared.

Hyde *et al.* (1992) suggest that such psychotic developments may owe much to the disruption of frontal-subcortical connections occasioned by the demyelination. At first this mainly affects the subfrontal and periventricular frontal white matter. As the disease progresses and demyelination spreads more diffusely the psychotic symptoms tend to disappear, being replaced by sensorimotor disturbances and dementia. However, the age of the patient must be an additional determining factor, since a similar distribution of demyelination is seen in the infantile, juvenile and late-onset forms.

A typical diagnostic puzzle is described below.

A woman of 29 was referred for a second opinion, 2.5 years after admission to a psychiatric hospital with a provisional diagnosis of schizophrenia. Certain organic features in her mental state had then given rise to concern. Her birth and early development had been normal, and her early schooling had proceeded smoothly. However, at 11 she changed, becoming increasingly disruptive and attention seeking. At 16 she was found to be of average intelligence but thought to have a personality disorder. On leaving school she held jobs for short periods only, and embarked on the life of a vagrant, obtaining money by petty theft and prostitution. Her behaviour became increasingly erratic and bizarre, and she gave birth to two illegitimate children whom she abandoned. All this was in contrast to her stable family background.

On a number of occasions, while on remand, she was found to be of average intelligence and a label of psychopathic personality was repeatedly applied. At 26 she was found wandering in a dishevelled state which led to her hospitalisation. On examination she was child-like and unable to give an account of herself. She repeated stereotyped phrases such as 'egg but no bacon', smiled fatuously, and would laugh or cry for no reason. She was uncooperative with cognitive testing and the initial diagnosis was of schizophrenia.

Ultimately it was possible to demonstrate grossly impaired short-term memory, poor writing and

constructional apraxia. Neurological examination showed primitive reflexes but no other abnormality. However, CT revealed considerable cerebral atrophy and lumbar puncture showed a raised CSF protein. Her WAIS verbal IQ was 59 and performance IQ 40.

On transfer to the Bethlem Royal Hospital she showed right-left disorientation, difficulty in following complex instructions and some nominal dysphasia. However, such features seemed to be in keeping with her level of global intellectual impairment. Neurological signs remained absent, but by now she was occasionally incontinent.

Extensive investigations revealed grossly deficient arylsulphatase A activity in the white blood cells and cultured skin fibroblasts. Metachromatic granules were present in the urine. EEG was normal, but the electromyogram showed slowing of sensory conduction in the lower limbs. A repeat CT scan showed more marked changes than before and MRI showed distinctive hyperintensities in the periventricular white matter (Fig. 14.3) (Fisher *et al.* 1987).

The specific diagnosis depends on showing diminished arylsulphatase A activity in the white blood cells, serum and urine, and demonstration of excessive sulphatide in the urine. Low levels of pseudoarylsulphatase A also occur in the absence of genetic variation in the gene, a condition known as pseudodeficiency. The clinical relevance of this is uncertain, although some studies have reported increased rates of pseudodeficiency in children with neurological signs and syndromes (Sangiorgi *et al.* 1991) not dissimilar to the clinical picture of children with diagnosed leucodystrophy (MacFaul *et al.* 1982) and adults with schizophrenia and other

psychotic disorders (Heavey *et al.* 1990; Mihaljevic-Peles *et al.* 2001).

Metachromatic deposits within Schwann cells may be detected in biopsy specimens from the sural nerve or rectal wall. Peripheral nerve conduction velocity is reduced. The heterozygote state may also be detected by measurement of arylsulphatase in the white blood cells. Waltz *et al.* (1987) emphasise the importance of brain imaging in bringing the disorder to mind, particularly in patients who present with psychiatric disorder. CT usually shows mild atrophy, with symmetrical decrease in white matter attenuation, especially near the frontal and occipital horns. MRI shows such changes more impressively.

At post-mortem severe white matter destruction is seen in the brain, often with cavitation, along with loss of normal myelin sheaths. Accumulations of strikingly metachromatic material appear as spherical granular masses. Similar changes are found in the peripheral nerves and certain visceral organs. The neuronal cell bodies are virtually unaffected, although at the end stage some may show sulphatide accumulations.

Kufs' disease (neuronal ceroid lipofuscinosis, Kufs-Parry disease, Batten-Bielschowsky or Spielmeyer-Vogt-Sjogren disease)

Kufs' disease is the name given to the adult form of cerebral lipidosis in which the abnormal lipopigment deposits consist of a ceroid-like material akin to lipofuscin. It is an example of one of many storage disorders usually evident in infancy and childhood. Interested readers should consult a textbook of paediatric neurology or recent reviews (Goebel & Wisniewski 2004; Rakheja *et al.* 2007) for details.

Symptoms begin in adolescence or adulthood with an insidious dementia accompanied by motor manifestations. Extrapyrarnidal disturbances and cerebellar disorder appear to be commoner than spasticity in adults. Myoclonic and other forms of seizure are often encountered. In a review of 118 published cases, Berkovic *et al.* (1988) accepted only 50 as true examples of the condition. The remainder showed a variety of atypical features or had evidence of other storage diseases (e.g. Niemann-Pick disease or late-onset gangliosidosis). Two main forms of clinical presentation were apparent: type A with seizures and type B with dementia and motor disturbances, although considerable overlap occurred. The seizures typically took the form of progressive myoclonus epilepsy, often with marked photosensitivity, proceeding ultimately to dementia. Neurological signs developed only late in type A patients and consisted of little more than ataxia and dysarthria. Type B patients usually presented with behavioural change, ranging from disinterest to overt psychosis, the organic nature of the condition becoming obvious when dementia or motor disturbances made an appearance. Cerebellar and extrapyramidal features were

Fig. 14.3 CT and MR scans from a patient with metachromatic leucodystrophy. (Reproduced from Fisher, N.R., Cope, S.J. & Lishman W.A. *Journal of Neurology, Neurosurgery and Psychiatry* (1987), **50**, 488–489, courtesy of BMJ Publishing Group.)

usually prominent, and tic-like facial dyskinesia particularly so. With both varieties the onset tended to be around 30 years of age, although some began in late adolescence. The course of the disease varied considerably, death following a mean of 12 years later.

Recessive inheritance predominates, although families with autosomal dominant inheritance have been described. A number of cases are apparently sporadic. The pathogenetic defect lies in the intracellular processing of lysosomal and perhaps of Golgi membranes. Unlike juvenile forms, there is no pigmentary degeneration of the retina.

Diagnostic classification of neuronal ceroid lipofuscinosis is based on age of onset, although there are other variants. A number of *CLN* genes have been identified (currently eight), mutations in which account for the varying phenotypes that lead to cellular accumulation of lysosomal storage material which ultrastructurally conforms to fingerprint or curvilinear profiles, or granular osmophilic deposits (Goebel & Wisniewski 2004). The diagnosis of adult neuronal ceroid lipofuscinosis is gained by careful evaluation of skin, rectal or brain biopsies with the electron microscope.

The characteristic finding at post-mortem is striking distension of nerve cells with autofluorescent lipopigment, along with neuronal degeneration and reactive gliosis. Cells in the basal ganglia, brainstem and cerebellum tend to be more heavily involved than those of the cortex (Dekaban & Herman 1974). A variable degree of generalised brain atrophy may accompany such changes.

Whipple's disease

Whipple's disease is a rare multisystem disorder that is infective in origin, the responsible organism being *Tropheryma whippelii* (Mahnel & Marth 2004; Deriban & Marth 2006). An immunological defect in the host is likely to play an important part in causation. It is very much more common in men than women, setting in usually in the sixth decade. The classic presentation is with weight loss, lassitude, chronic diarrhoea and malabsorption, often pursuing a chronic course to extreme emaciation. Multiple arthralgias, serous effusions, uveitis, lymphadenopathy and low-grade pyrexia are other common manifestations.

Involvement of the nervous system occurs sometimes after the systemic disorder is well advanced but occasionally as the dominant feature. Neurological involvement has been reported several times when gastrointestinal and other symptoms are minimal. In very rare examples it has represented the sole clinical or pathological manifestation of the disorder. Louis *et al.* (1996) note that the diagnosis should be considered in any case of systemic illness accompanied by supranuclear vertical gaze palsy, rhythmic myoclonus, dementia with psychiatric symptoms, or hypothalamic manifestations.

The symptoms tend to be non-specific so that diagnosis may be missed or greatly delayed. Pallis and Lewis (1980)

describe the common picture as dementia progressing over months or years, external ophthalmoplegias, or myoclonic movements of the head, trunk or limbs. Other patients have presented with focal neurological signs indicative of a space-occupying lesion, or hypothalamic involvement with somnolence, hyperphagia and polydipsia. A slowly progressive dementia has been described in several patients. It may be accompanied by motor disorder, particularly supranuclear gaze palsies or myoclonus, although such are not always in evidence. Lampert *et al.*'s (1962) patient had a 7-year history of progressive mental deterioration leading to an impression of Alzheimer's disease; there was no history of gastrointestinal disturbance though an attack of arthritis had occurred at the onset.

Evidence of malabsorption or anaemia will often be present. The CSF may be normal or show pleocytosis and elevation of protein. The CT scan can be negative, although may show hyperdense regions in the white matter (Ludwig *et al.* 1981). Definitive diagnosis depends on the demonstration of periodic acid-Schiff (PAS)-positive material in macrophages which, in the absence of prior treatment, can almost always be revealed by duodenal biopsy. This must be undertaken whenever the disease is suspected. Lymph node biopsy can be informative too, or the characteristic inclusions may be detected in cells from the CSF. Polymerase chain reaction amplification of the CSF may be performed to detect the DNA sequence specific for *T. whippelii*. Brain biopsy will sometimes be performed (Warren *et al.* 2005), but will stand to be negative in patients with hypothalamic involvement alone.

The findings at post-mortem are distinctive. Tissues involved by the disease show PAS-positive granules within macrophages, representing membrane-like structures derived from bacterial walls (sickle particle-containing cells). The bacilli themselves can sometimes be seen by electron microscopy. CNS involvement shows as collections of PAS-positive cells in the brain and cord, often with widespread perivascular nodules and indolent inflammatory changes.

Treatment with antibiotics usually meets with a good response where gastrointestinal and other systemic manifestations are concerned. In the treatment of neurological complications less success has been reported, although a vigorous attempt should always be pursued. Albers *et al.* (1989) discuss the various treatment regimens employed, emphasising the importance of using antibiotics that cross the blood-brain barrier if neurological involvement is to be controlled.

Mitochondrial myopathy (mitochondrial encephalomyopathy)

The mitochondrial myopathies are a complex group of diseases that share in common a primary dysfunction of mitochondrial metabolism (see De 1993 for a review of these syndromes). Although first described in relation to skeletal

muscle, many other organs may be affected, leading sometimes to dysfunction in the liver, heart, kidney, eye or endocrine system (so-called multisystem disease). The CNS is frequently involved and neuropsychiatric disorder can be the predominant manifestation (mitochondrial encephalomyopathy).

The underlying defects in mitochondrial metabolism have been studied in detail, revealing deficiencies in various respiratory chain enzymes, especially complexes I and III. At present, however, the relationship between such defects and the phenotypic manifestations of disease show a good deal of overlap and precise systems of classification have not been achieved. Molecular biological approaches have revealed several point mutations as well as rearrangements of mitochondrial DNA such as partial deletions or duplications (Di Mauro & Moses 1992). However, the nuclear genome also encodes extensively for mitochondrial proteins and may often be involved (Shanske 1992). Mitochondrial myopathies associated with point mutations (e.g. MERRF and MELAS, see below) usually show a maternal pattern of inheritance, whereas large-scale mitochondrial DNA deletions are generally sporadic (Oldfors *et al.* 2006).

A number of clinical syndromes are now well recognised, as reviewed by Lombes *et al.* (1989). Mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes (MELAS) is the most common maternally inherited mitochondrial disease and may present in children or young adults with stunted growth, seizures and episodic vomiting. Recurrent stroke-like episodes are characteristic with transient hemiplegia, hemianopia or cortical blindness. An A→G mutation in the transfer RNA^{Leu(UUR)} at position 3243 of the mitochondrial DNA accounts for the majority of MELAS cases (Wallace 1992). However, the clinical phenotypes associated with this point mutation are diverse. Chronic progressive external ophthalmoplegia (CPEO) (Mariotti *et al.* 1995) and Leigh syndrome (Makino *et al.* 2000) have also been associated with the A3243G mutation. Kearns–Sayre syndrome is defined by the triad of progressive external ophthalmoplegia, pigmentary retinopathy and cardiac conduction defects, usually with onset before the age of 20 years (Gross-Jendroska *et al.* 1992). The most common molecular defect underlying Kearns–Sayre syndrome is large-scale deletions of mitochondrial DNA (Zeviani *et al.* 1998). Myoclonus epilepsy with ragged red fibres (MERRF) presents with myoclonus, ataxia and muscle weakness and often progresses to generalised seizures and dementia. Onset is again usually before the age of 20. The most common point mutation associated with this condition is at nucleotide 8344 (A8344G) of the tRNA(Lys) gene of mitochondrial DNA (Oldfors *et al.* 1995).

However, the pleomorphic manifestations of mitochondrial disorders do not fit neatly into distinct subsyndromes. Petty *et al.* (1986) reviewed 66 cases. Onset in the majority was before 20 years of age, but presentations occurred up to the age of 68. Relatives were affected in almost one-third of

cases. Petty *et al.* made a broad division into three groups. The commonest presentation (55% of cases) was with ptosis, progressive external ophthalmoplegia, and limb weakness induced or increased by exertion. A further 18% presented with limb weakness alone, showing a proximal myopathy with exercise intolerance. These could continue with muscle involvement alone, although a few patients developed neurological manifestations later. The remaining 27% showed predominant involvement of the CNS, with features such as ataxia, deafness, involuntary movements and seizures. Dementia was common in this last group and was severe in many. Whereas overall prognosis was good in patients without CNS involvement the last group fared poorly, half of them becoming dependent on others at a mean of 17 years from onset.

A mitochondrial myopathy will usually be suspected in patients who present with progressive external ophthalmoplegia combined with other symptoms, or when myopathy is accompanied by prominent fatigue. Petty *et al.* suggest that it should also be considered in the absence of such symptoms when there is cerebellar ataxia, deafness or pigmentary retinopathy, and especially when these are combined with involuntary movements or dementia.

Talley and Faber (1989) report a man of 26 suffering from MELAS syndrome who presented with dementia. Admission to hospital was precipitated by failing memory and social withdrawal 1 month after an episode of status epilepticus. He was short in stature and showed a right visual field defect, diminished hearing and neglect of the right upper extremity. Though initially orientated in time and place he was slowed, and his speech was limited to stereotyped phrases. He was unable to read, perform simple calculations or copy geometric figures. His prevailing mood was of apprehension. EEG showed diffuse slowing, and CT revealed calcification in the basal ganglia and right thalamus. Lactic acid levels were raised in the blood and CSF, and muscle biopsy showed diffuse ragged red fibres.

Over the next 3 weeks he became mute, markedly indifferent to what went on around, and with a severe comprehension defect. He developed hemiparesis on the right, and a left visual field defect in addition to the right hemianopia. New findings on CT included lucent areas medially in the left hemisphere. Major seizures developed and he became combative and difficult to manage. Repeated hospitalisations were required on this account over the succeeding 4 years, with periodic stroke-like events, generalised seizures and a fluctuating though declining level of mentation. The patient's mother was of short stature with bilateral sensorineural hearing loss, easy fatigability and ragged red fibres on muscle biopsy. His half-sister similarly showed indications of MELAS syndrome.

The decisive investigation in mitochondrial myopathies is skeletal muscle biopsy. The appearance of ragged red fibres with the Gomori trichrome stain is almost pathognomonic, representing abnormal accumulations of mitochondria. Histochemical staining techniques such as demonstration of strongly succinate dehydrogenase-reactive blood vessels and electron microscopy provide confirmatory information; subsarcolemmal mitochondria are abnormal in size and morphology as well as increased in numbers. Skeletal muscle tissue obtained by biopsy is also useful for the preparation of intact mitochondria for assaying respiratory enzyme activities, which are frequently abnormal (Thambisetty & Newman 2004).

Other important investigations include raised resting blood lactate levels, or when normal are increased on exercise. Electromyography may show myopathic changes, and CSF protein may be raised. Infarct-like lucencies on CT are a common feature with involvement of the CNS; in MELAS, these hypodensities are transient, correlating with fluctuations in the clinical course. CT or MRI is also likely to show cerebral or cerebellar atrophy with calcification of the basal ganglia also being reported (Thambisetty *et al.* 2002).

Behçet's syndrome

Behçet's syndrome is an uncommon disorder predominantly affecting young males. It is rare in childhood and in persons over 50. It is said to be more common in Mediterranean countries, the Middle East and Japan but occurs worldwide. The classic triple symptom complex consists of oral ulceration, genital ulceration and ocular lesions (uveitis, iridocyclitis, retinal vasculitis), usually occurring in several attacks per year and pursuing a chronic course over many years. Lassitude, malaise and slight pyrexia may accompany attacks but the degree of constitutional disturbance varies. Common additional manifestations include arthritis, thrombophlebitis, erythema nodosum and non-specific skin sensitivity. The overall course is unpredictable, but the illness often abates after one or two decades. Blindness may remain as a permanent sequel.

It is now recognised to be a chronic multisystem disorder with predominant vasculitis (Wechsler & Piette 1992). Diagnostic criteria have been proposed but there is no universally accepted diagnostic test (International Study Group for Behçet's Disease 1990). CNS involvement is recognised as a serious complication, important not for its frequency but on account of its grave prognosis. No part of the nervous system appears to be immune. A great variety of clinical pictures may result from the vasculitis and disseminated encephalomyelitis.

The onset is usually abrupt, coinciding with a relapse of orogenital ulceration or uveitis. Failing this there is almost always a well-established history of the syndrome before nervous system involvement sets in. The patient develops

headaches, fever, slight neck stiffness and a variety of neurological signs. Brainstem involvement is particularly common, with giddiness, ataxia, diplopia, cranial nerve palsies or long tract signs. A typical feature is the episodic nature of such defects, the picture seeming to stabilise after several weeks then relapsing with fresh developments. Recurrent attacks of hemiplegia or paraplegia may lead on to pseudobulbar palsy. Periods of remission may result in temporary improvement or in rare cases complete recovery. In general, however, serious neurological defects persist. The course has been likened to that of severe forms of MS and differentiation may occasionally present difficulties (Ashjzadeh *et al.* 2003). Dural venous sinus thrombosis has been found to be common, often presenting with intracranial hypertension (Wechsler *et al.* 1992). The CSF usually shows a slight lymphocytic pleocytosis and increase in protein. When neck stiffness is severe there may be a marked polymorphonuclear response.

Pallis and Fudge (1956) attempted to demarcate three main forms of nervous system involvement: a brainstem form, a meningo-myelitic form and a variety with mental symptoms predominating. The last could present either as transient episodes of confusion or in the form of dementia. The patients with dementia usually showed an insidious onset and steady slow progression, sometimes accompanied by features of parkinsonism and sometimes by pseudobulbar palsy. Executive dysfunction and memory impairment occurs even in the absence of overt neurological symptoms and depression (Monastero *et al.* 2004; Erberk-Ozen *et al.* 2006). Depression is common, affecting up to half of all patients, and adversely impacts on quality of life (Taner *et al.* 2007; Uguz *et al.* 2007). Schizoaffective and bipolar symptoms have also been reported, sometimes in multiple members of affected families (Goolamali *et al.* 1976; Berman *et al.* 1979; Alevizos *et al.* 2004).

Involvement of the CNS is usually a serious development. The patient's general condition is often poor, and adverse developments can set in rapidly. However, the course of each episode is unique and unpredictable. Some patients deteriorate after repeated relapses, some remain quiescent for long periods, and others decline steadily and die.

Computed tomography may show single or multiple low-density lesions, principally in the subcortical nuclear masses or brainstem, often with resolution some weeks later. Atrophic changes are also common, with an accent on the posterior fossa cisterns and cerebellar sulci. MRI is more sensitive in revealing focal areas of altered signal intensity (Mizukami *et al.* 1992), and may be especially valuable in showing dural sinus thrombosis. Periventricular lesions similar to those of MS may be seen. Changes at post-mortem include low-grade perivascular inflammation, scattered areas of demyelination and necrosis, and patchy cerebral infarction.

As might be expected in an inflammatory condition, plasma levels of cytokines and also leptin, a proinflammatory

matory mediator, are elevated but are not diagnostic (Evereklioglu *et al.* 2002a,b). The disease tends to aggregate in families but without good evidence for mendelian patterns of inheritance in most cases. The exception are those very rare cases of paediatric onset, which appear to be largely autosomal recessive (Molinari *et al.* 2003). Genetic linkage of Behçet's disease to the HLA-B region has been established (Ohno *et al.* 1982; Ando *et al.* 1997) but the precise genetic variant associated with disease remains to be discovered.

Treatment is entirely symptomatic or palliative (Evereklioglu 2004). Steroids have been claimed to help markedly in some patients, including those with involvement of the CNS, although others have reported no benefit. Immunosuppressive drugs (cyclophosphamide, azathioprine, chlorambucil) may also be of benefit, though side effects limit their usefulness. Other approaches are under investigation including thalidomide and monoclonal antibodies to tumour necrosis factor (TNF)- α and other cytokines (Evereklioglu 2004).

Sarcoidosis

Sarcoidosis is characterised by the development of chronic granulomatous lesions in various parts of the body. The aetiology is unknown, though an immunologically determined alteration in tissue reactivity appears to be fundamental to the disease. It is assumed, but not proven, that this is induced by exposure to some environmental, perhaps infectious, agent. The immunological profile is complex, with an increase in CD4⁺ helper T cells and yet at the same time a frequent reduction in reaction to immunological challenge; in other words, a combination of activation and suppression profiles. A familial aggregation has long been noted, although this does not appear to fall into any recognised pattern of inheritance (Buck & McKusick 1961). Association with a variety of HLA profiles has been noted (Nowack & Goebel 1987; Rossman *et al.* 2003) and currently the most promising markers of disease are the HLA-DRB1 locus and the *BTNL2* gene, which appears to be an independent susceptibility factor even though it maps close to the HLA-DRB1 locus itself.

The characteristic lesion is the epithelioid cell granuloma or follicle, consisting of a well-demarcated collection of epithelioid cells with occasional giant cells. The centres may show necrosis but the caseation seen with tubercular infection is lacking. The lesions tend to heal spontaneously but provoke surrounding fibrosis. The commonest site is the respiratory system, presenting with hilar lymphadenopathy or reticular shadowing in the lungs. The mildness of symptoms often contrasts with the extent of the lesions, cases sometimes being discovered on routine chest radiography. Erythema nodosum is another characteristic presentation. Ocular manifestations include iridocyclitis and uveitis. The latter

may be accompanied by parotitis (uveoparotid fever). Other parts of the body commonly involved are the superficial lymph nodes, spleen, liver and phalanges of the hands and feet. Overt myopathy is rare but muscle infiltration is often apparent on biopsy.

The onset is usually between the ages of 20 and 40 years. In general sarcoidosis runs an indolent course with relapses and remissions, showing a tendency to subside spontaneously after several years. Individual lesions gradually resolve while others make an appearance, the cycle sometimes being narrowly confined and sometimes widespread in different organs. A minority of patients are left disabled by pulmonary fibrosis or ocular complications. Death, when it occurs, may be due to renal failure or cardiac involvement. Affection of the CNS (see below) can also carry serious hazards. Treatment with steroids is often effective in inducing remission and promoting the healing of lesions, although maintenance therapy must sometimes continue for many years. Immunosuppressive therapy plays a role and newer treatments are emerging (Baughman *et al.* 2003; Grutters & van den Bosch 2006).

A low-grade pyrexia is an inconstant accompaniment. During active phases of the disease there may be a normochromic anaemia, raised erythrocyte sedimentation rate and eosinophilia. Mild leucopenia and thrombocytopenia are sometimes seen. The serum immunoglobulins, especially IgG, are usually elevated and hypercalcaemia of moderate degree is not infrequent. In uncertain cases and with unusual presentations chest radiography may reveal the characteristic picture, likewise radiograph of the phalanges. A raised serum alkaline phosphatase denotes hepatic involvement. Biopsy of skin lesions, lymph nodes or muscle can give confirmatory evidence. The Kveim test consists of an intradermal injection of sarcoid tissue extract; this has fair reliability, yielding a nodule with the histological features of sarcoidosis.

Involvement of the nervous system is estimated to occur in 5% of patients (Vinas & Rengachary 2001; Stern 2004; Joseph & Scolding 2007). Neurological dysfunction may be the presenting feature or indeed the sole clinical manifestation, although cases with lesions entirely confined to the nervous system are very rare (Allen *et al.* 2003). There are no clear demarcations between the various forms of nervous system involvement but certain broad categories can be discerned. The parts most frequently involved are the cranial nerves, meninges, hypothalamus and pituitary.

Lesions of the cranial and peripheral nerves are the commonest neurological feature. The seventh cranial nerve is particularly vulnerable, leading to unilateral or bilateral facial palsies. Involvement of the optic nerves results in blurring of vision, papilloedema, optic atrophy or field defects. The peripheral nerves may be affected singly or in combination. Basal meningitis or brainstem involvement can lead to multiple fluctuating cranial nerve palsies.

Granulomatous meningitis or meningoencephalitis affects mainly the basal brain regions. The meninges become thickened and infiltrated with granulomas and lymphocytes. Lumbar puncture shows elevated protein and a pleocytosis. Chronic headache is accompanied by focal signs as the adjacent chiasm and hypothalamus become infiltrated. An adhesive arachnoiditis can lead to raised intracranial pressure and hydrocephalus. In some cases the meningeal involvement remains entirely subclinical; it was evident in all 14 of Delaney's (1977) post-mortem cases, yet had been suspected during life in only nine.

The brain parenchyma may become involved by contiguous spread or by the formation of tumour-like masses of granulomatous material. Involvement of the hypothalamus and third ventricular region leads to somnolence, obesity, hyperthermia and memory difficulties or change of personality. Pituitary dysfunction may show as diabetes insipidus, menstrual irregularities and other endocrine dysfunctions. Lesions situated within the cerebral hemispheres may be single or multiple. The cerebellum, brainstem or cord may be similarly affected. Solitary deposits have sometimes been mistaken for neoplasms until biopsy is performed. Focal signs may make an abrupt appearance, and seizures can be hard to control.

Mental disturbance will often be prominent when sarcoidosis affects the CNS. Hook (1954) reported patients with a variety of pictures: apathy, lack of judgement and personal neglect progressing over a year to semicomatose; acute agitation and hallucinosis leading to residual dementia; profound memory impairment and irritability. Friedman and Gould (2002) similarly report a patient with confusion and psychosis, and others report neurosarcoid presenting as schizophrenia (Duwe & Turetsky 2002; Zielasek *et al.* 2002). Cordingley *et al.*'s (1981) patient presented with progressive dementia, the only abnormal signs being a wide-based gait and incomplete eye abduction together with nystagmus on lateral gaze. Others have described marked changes of character, fluctuating confusion and a variety of psychotic pictures. In some the disturbance will be occasioned by hydrocephalus consequent on basal meningitis or obstruction of CSF flow by granulomatous masses. In others direct brain infiltration will be responsible. In patients with circumscribed failure of memory, as in the following example, localised involvement of the hypothalamus and limbic structures is probably responsible.

A woman developed sarcoidosis at 24, presenting with bilateral hilar lymphadenopathy. Two years later she had a minor seizure and shortly thereafter developed headache, weakness and incoordination. Examination revealed a sensory level at T4 and a myelogram showed obstruction from T4 to T7. CT demonstrated a right frontal granuloma

and basal meningeal involvement with mild ventricular dilatation. Dexamethasone produced marked neurological improvement over the following year which was well maintained.

At 28 she became aware of increasing memory impairment over 3–4 weeks, then abruptly became agitated, deluded and doubly incontinent. She was disorientated in time and place and heard hallucinatory voices at night. The acute organic reaction settled over 6–8 weeks on haloperidol and increased dexamethasone, but her memory remained mildly impaired. Psychometric testing at that time showed a WAIS full scale IQ of 78, with scores of 55% on the Wechsler Logical Memory Test and 45% on the Rey–Osterrieth Test.

Some months later her memory deteriorated further and she developed compulsive eating, weight gain and insomnia. At 30 she was obese, mildly ataxic, and with hyperreflexia in the legs and bilateral extensor plantars. There were no psychotic features but she was disorientated in time and showed a severe defect of short-term memory. She could recall nothing of a name and address or of simple geometrical figures. The WAIS IQ was 82, but the logical memory test now gave a score of only 20% and the Rey–Osterrieth Test 30%. The CT scan was unchanged but pulmonary and hepatic involvement was demonstrated. Steroids were increased to high dosage, with improvement 3 weeks later in orientation and on simple tests of recall. She was discharged to a semi-independent life in her own home which she managed to run with the help of memory aids (Thompson & Checkley 1981).

A further instructive patient was reported by McLoughlin and McKeon (1991), in whom both memory disorder and bipolar affective disorder appeared to be due to involvement of the limbic system.

A 25-year-old mechanic developed hilar lymphadenopathy, and sarcoidosis was confirmed by mediastinoscopy and lymph node biopsy. This resolved with steroids and he remained well for 6 years until sarcoid meningitis appeared. This too resolved with steroids over a number of months and he remained on prednisolone 15 mg daily thereafter. Three years later, at the age of 34, he developed sensorimotor leg neuropathies and bilateral fifth nerve numbness, but CT at this time showed no cerebral abnormalities. Two years later he developed diabetes insipidus and anterior pituitary failure requiring replacement therapy, and the following year was treated with cranial irradiation. CSF analysis showed active CNS sarcoidosis and MRI revealed minimal cortical atrophy.

The following year he became depressed with anorexia, weight loss and marked guilt feelings about his illness. There was no family history of psychiatric disorder. At the same time he noted that his memory was impaired for recent events. Imipramine relieved the depression, but 12 months later he began to experience marked mood swings alternating between episodes of depression and hypomania lasting for a few days at a time. Three months later lithium was added, by which time the mood swings were alternating every 24–28 hours. Neurological examination was normal apart from bilateral facial sensory impairment. CSF analysis showed that the neurosarcoidosis was still active, but repeat MRI showed no change. Psychometric testing confirmed the memory deficit and showed a WAIS-RIQ of 96.

Attempts to stabilise his mood swings with high-dose lithium failed on account of troublesome polyuria, but they nevertheless subsided over several months in hospital. He remained depressed and some months later took an overdose and died. At post-mortem a large granulomatous mass was discovered just anterior to the mamillary bodies at the origin of the pituitary stalk. Histological examination showed that this had infiltrated the dorsomedial nucleus of the thalamus, mamillary bodies, third ventricle, fornices and pituitary stalk. There was patchy basal meningeal fibrosis with isolated meningeal granulomas. The cerebral hemispheres, cerebellum and brainstem were unaffected. Spinal meningeal fibrosis was severe with entrapment of ventral and dorsal roots.

In some cases a combination of structural and metabolic disturbances is likely to shape the psychiatric picture, particularly in the presence of hypercalcaemia or a degree of renal failure. Steroid therapy may make its own contribution to mental disturbances.

In patients with organic psychosyndromes and neurological defects of obscure origin, it is obviously important to bear the possibility of sarcoidosis in mind. Full investigation along the lines described above will almost certainly produce confirmatory evidence of the disorder, even when nervous system involvement has been the presenting manifestation. Neuroimaging may show the intracranial lesions or evidence of basal meningitis, and lumbar puncture may reveal evidence of chronic meningitis.

The prognosis for patients with neuropsychiatric complications is extremely variable, but in general intracranial involvement should be viewed as a grave development. Some show a remittent picture, others slow and incomplete recovery, while others show progressive disability. A few will die of the neurological manifestations. However, the outlook is not uniformly poor. Among the 19 patients followed by Pentland *et al.* (1985), half had had an acute monophasic illness which resolved with steroids, and alto-

gether two-thirds showed a surprisingly good outcome 1–16 years later. Those who had shown a relapsing–remitting course had often presented pictures closely simulating MS. Facial nerve palsy is usually transient and shows a good response to steroids. Basal meningitis may slowly ameliorate and subside, although the overall response to treatment is poor. In favourable cases intracerebral granulomas can improve or even resolve with steroid therapy, and surgical removal has occasionally been successful.

Electrical accidents and lightning injuries

Contact with powerful sources of electric current may cause sudden death due to ventricular fibrillation or respiratory arrest, sometimes with severe burns where the current enters and leaves the body. The effects of the shock are strongly influenced by the site of contact as well as the strength of the electrical source. Among survivors transient evidence of neurological dysfunction is not uncommon, although persisting sequelae appear to be rare. The mortality in 60 cases reported by Hammond and Ward (1988) was 3%; neurological complications were noted in one-quarter and psychiatric sequelae in 18%. Psychiatric and neurological sequelae of electrical trauma have been reviewed (Kotagal *et al.* 1982; van Zomeren *et al.* 1998; Duff & McCaffrey 2001; Primeau 2005).

Much of the acute disturbance appears to be due to temporary blockade of neuronal function or vasomotor changes in the brain and cord, although petechial haemorrhages and areas of demyelination and degeneration have been observed. Additional damage may be caused by intense tetanic muscular contractions that sometimes propel the victim for a considerable distance. Acute tetanic spasm of the paraspinal muscles may produce compression fractures of the vertebral bodies. With lightning injuries blast-like lesions may be sustained due to the sudden displacement and return of air in the immediate vicinity of the lightning strike.

A period of unconsciousness may last for hours or days, sometimes being delayed for several moments during which the affected person calls for help. The unconsciousness may be accompanied by epileptic seizures or more commonly myoclonic jerking. Cessation of respiration due to bulbar paralysis can require assisted ventilation for many hours. When consciousness is retained the subject may experience intense pain, tinnitus, deafness or visual disturbance, along with tremors, twitching, local paralysis and sensory changes. Confusion and excitement can then be prominent, with retrograde and post-traumatic amnesia much as with head injury. Severe neurological disturbances such as paraplegia, hemiplegia, mutism and aphonia may resolve over hours or days. Transient unilateral parkinsonism has been attributed to damage to the basal ganglia. Fixed dilated pupils during the acute stage are not necessarily an ominous prognostic sign. All patients should have electrocardiographic

monitoring for at least 48 hours to enable detection of cardiac dysrhythmias, and a watch must be kept for acute renal failure due to myoglobin released from injured muscles (Pruitt & Mason 1996).

More prolonged sequelae include cranial nerve damage with loss of taste, facial paresis and auditory and vestibular disturbances. Very occasionally, severe diffuse brain damage may be an enduring aftermath. However, the most common sequelae are peripheral nerve and spinal cord syndromes that are sometimes days or weeks in developing, perhaps as vascular changes progress. Farrell and Starr (1968) stress that a latent period of months may occasionally intervene. The pictures that have been described include delayed atrophy affecting an arm or leg, quadriplegia, or slowly progressive spasticity with sensory changes (so-called spinal atrophic paralysis). The waxing and waning of chronic neurological deficits may sometimes resemble MS. In patients such as these the current may have traversed the spinal cord directly.

Prolonged neuropsychiatric aftermaths include amnesia and impaired cognitive functioning, often compounded by anxiety attaching to the shock and sometimes by compensation issues. Of 60 patients in Hammond and Ward's (1988) series, 11 suffered psychiatric problems similar to those of post-traumatic stress disorder: insomnia, nightmares, anxiety, headache and difficulty in concentration. The following patient illustrates the cognitive and personality changes that may occasionally follow.

A 26-year-old man was rendered unconscious for several hours after sustaining a shock from bare wires which had made contact with his forehead. On recovery he had throbbing headache, was sluggish in cerebration, and complained of feeling depressed and irritable for several weeks thereafter. CT was normal. Two months later he was still vague and forgetful with delayed responses to questions. Five months after the accident he showed significant impairment of memory, lability of mood and psychomotor retardation. His girlfriend described a marked change of personality, with argumentativeness and occasional aggressive behaviour. Cognitive testing showed nominal and expressive dysphasia, impaired right-left discrimination, and difficulty in making simple drawings. He had lost his ability to speak German, which he had learned during the previous 3 years. WAIS scores were well below expectation in view of his educational and occupational history.

Two years later his memory remained impaired and he was still mentally sluggish and rather vacuous in appearance. However, there was no longer evidence of dysphasia or drawing difficulties. Simple arithmetic was poor. His mother confirmed a marked change of personality from a bright extroverted person to one who was slow, sullen and withdrawn. Though no longer depressed he was distractible, and had abandoned his reading and former hobbies.

Brain injury due to diving

Apart from the hazards of anoxia and hypothermia, divers are at risk of two main forms of injury to the nervous system, namely toxicity due to gases breathed under high partial pressure and decompression illness (DCI). These risks increase in relation to the depth and duration of submersion and, perhaps not surprisingly, are increased in younger and less experienced divers (Newton *et al.* 2007). They apply equally to caisson workers who may spend several days at a time working at very considerable depths. When explosives are used divers are also exposed to increased risk of blast injury because of the enhanced transmission of pressure waves in water.

There are also concerns that divers, including sports divers, may sometimes sustain a degree of neurological damage even in the absence of obvious events such as DCI, although the issue remains controversial. Repeated exposures appear to be a special hazard in persons with a patent foramen ovale or other form of right-to-left shunt in the circulation. These matters are considered below, much deriving from accounts by Denison (1996) and Wilmshurst (1997).

Gas toxicity

The gases breathed during submersion must be delivered at the same pressure as the surrounding water. Scuba divers breathe compressed air but are restricted to relatively shallow depths (30–50 m) because of the risk of nitrogen narcosis, which is probably due to the narcotic effects of nitrogen dissolved in nerve membranes impeding neural transmission. The breathing of pure oxygen does not solve the problem, because oxygen is toxic to the lungs when alveolar pressure exceeds 50 kPa (0.5 atmospheres, 5 m of sea water) and to the nervous system when the pressure exceeds 200 kPa (2 atmospheres, 10 m of sea water). Epileptic convulsions are then liable to occur. Deeper dives are accomplished using a mix of oxygen and helium and this has allowed divers to reach astonishing depths (below 600 m). However, deeper than 160 m the risk of high-pressure nervous syndrome increases considerably, resulting in tremor, myoclonic jerks, nausea, vomiting, fatigue, postural instability, somnolence and cognitive dysfunction and other symptoms (Bennett & McLeod 1984).

Decompression illness

During submersion inert gases under pressure become dissolved in body tissues: nitrogen when breathing air, or helium when breathing oxygen-helium mixtures. In the course of the ascent such gases come out of solution as the ambient pressure falls, tending to form bubbles within the tissues and the blood (gas nucleation). Provided the ascent is sufficiently gradual the extra load of gas diffuses into the bloodstream and out of the lungs, but if it is too rapid the bubbles increase in size and number and may come to block blood vessels. This appears to be the principal

cause of DCI or 'bends', which is a risk with any dive below 10 m unless very brief. It is a particular risk after deep 'saturation dives', during which divers are maintained at the pressure of their diving depth for days or weeks on end; chambers are used at the surface for this purpose, to economise the time which would otherwise be needed for repeated very slow ascents.

Two grades of DCI are recognised: type 1 bends, consisting of skin irritation and musculoskeletal pain only; and type 2 bends, with pulmonary and nervous system manifestations and sometimes circulatory collapse. Pulmonary symptoms consist of sudden chest pain, dyspnoea and cough due to bubble formation within the pulmonary circulation. Neurological symptoms, which occur in about half of cases, consist chiefly of spinal cord syndromes, visual disturbances or vertigo, although central focal deficits may occur. Newton *et al.* (2007) review 200 cases of DCI and report that over 85% of these had at least some neurological manifestation. The range of severity is wide, from slight dysaesthesiae, ataxia and ophthalmoplegia to paraparesis, quadriplegia, dysphasia and confusion. Such episodes may be transient or long-lasting and permanent sequelae can result. The episodes are sometimes recurrent, in general resembling thromboembolic cerebrovascular disease except for commonly affecting the cord. The symptoms usually develop some minutes to hours after the dive is over, and must be treated immediately by recompression and the administration of oxygen. The diversity of symptoms associated with DCI may sometimes suggest that psychiatric syndromes occurring in divers might be atypical DCI episodes. Hopkins and Weaver (2001) report two such cases where a psychotic episode occurred in the context of a dive and possible DCI. However, careful consideration of the symptoms, which included muscle pain, weakness and fatigue, made the primary diagnosis of DCI unlikely and treatment with hyperbaric oxygen did not result in a reversal of the psychosis.

Severe examples of DCI may result from a different mechanism, when lung tissue becomes disrupted by the expansion of gases within it (pulmonary barotrauma), allowing gas to enter the pulmonary veins and thus the arterial system. Cerebral gas embolism may then result in severe focal cerebral symptoms. However, the distinction between pulmonary barotrauma and gas nucleation in leading to the various manifestations of DCI is far from established.

Neuropathological effects apparently related to DCI have been described by Palmer *et al.* (1987). In an examination of the spinal cords of 11 divers, mostly dying from diving accidents, they found distended empty blood vessels, sometimes with perivascular haemorrhages, and minor chronic changes with foci of gliosis and hyalinisation of blood vessels. In three cases Marchi staining showed tract degeneration, variously affecting the posterior, lateral or anterior columns of the cord. Examination of the brains of 25 divers, again mostly dying from diving accidents, showed distended empty vessels in two-thirds of subjects, presumably caused by gas bubbles

(Palmer *et al.* 1992). Perivascular lacunae were present in one-third, presumably due to bubble occlusion, along with hyalinisation of blood vessels which may have accrued from periodic rises in luminal pressure. Foci of necrosis were sometimes observed in the cerebral grey matter, and vacuolation in the white matter extending to status spongiosis.

Sequelae of diving

A well-known long-term effect of diving is the presence of aseptic infarcts in the long bones, evident on radiography and presumably due to gas embolism. This is commoner with a history of DCI but is found in many subjects with no such history. The incidence rises with age and diving intensity. Infarcts near the articular surfaces can be severely disabling, and crippling dysbaric osteonecrosis may occasionally ensue.

The neurological disturbances of DCI may fail to resolve completely, and surveys of divers have shown a small but definite prevalence of neurological deficits. Todnem *et al.* (1990) examined 156 commercial divers, aged 21–49 years, along with 100 controls. Half of the divers had experienced frank episodes of DCI. At the time of examination 20% had stopped diving and six had lost their licenses because of neurological problems; 12 (8%) had had problems with vision, vertigo or reduced skin sensitivity in non-diving situations, and six had been referred to neurological clinics on account of seizures, transient cerebral ischaemia or transient amnesia attacks. No controls had such symptoms. The divers complained significantly more often of symptoms referable to the CNS, mainly problems with concentration and memory, and had more peripheral neurological symptoms, chiefly paraesthesiae in the hands and feet. On examination significantly more showed hand tremor, or signs indicative of cord damage such as reduced touch and pain sensation in the feet. Seven had a mild peripheral neuropathy. Scores for neurological symptoms and signs correlated significantly with age, amount of diving exposure, and a history of DCI. In another self-report study, divers with experience of DCI reported considerably more long-term neurological sequelae than other divers (McQueen *et al.* 1994). In a study of construction divers matched to controls, the divers had significantly different error rates in tasks of reference memory and navigation behaviours (Leplow *et al.* 2001). In another investigation of saturation divers, Todnem *et al.* (1991a) found that 18% of divers and 5% of controls had abnormal EEG, with increased temporal slow waves and sharp potentials. Such abnormalities again correlated significantly with diving exposure and a history of DCI but not with neurological symptom scores. Brainstem evoked potential latencies were also increased in the diving group.

Shallow water diving is a variant used professionally for collection of shellfish and recreationally, where instead of using scuba equipment the divers hold their breath. Deep water 'free diving' is a particularly risky and difficult

recreational variant of unassisted diving. Neurological sequelae of shallow water diving, including cognitive and motor deficits, result from DCI and from carbon monoxide poisoning (Williamson *et al.* 1987). In a large study of professional abalone divers the incidence of deficits in visual function, psychomotor abilities and recent memory was related to individual characteristics in the divers and attributed to their diving technique (Williamson *et al.* 1989).

A recent cause for concern is the demonstration of hyperintensities on MRI in a proportion of divers and caisson workers, presumably due to microinfarcts in the brain (Warren *et al.* 1988). Reul *et al.* (1995) studied 52 amateur scuba divers (mean age 38 years) and compared them with 50 controls engaged in other sports; 52% of the divers and 20% of the controls showed hyperintensities, principally in the subcortical white matter and basal ganglia. These were significantly larger and more numerous in the divers. Only three had histories pointing to episodes of DCI, suggesting that such lesions may often accrue without clinical indicators of their presence. Others, however, have found no excess of MRI abnormalities in divers compared with controls (Rinck *et al.* 1991; Todnem *et al.* 1991a,b), perhaps due to different selection procedures and imaging protocols. In some studies although no excess of MRI abnormalities was observed in divers, those that were found correlated with faster rate of ascent and other variables suggestive of dive-related events (Tripodi *et al.* 2004). Hyperbaric oxygen exposure in the absence of DCI (in chamber attendants for example) does not appear to be associated with neurological problems or MRI lesions (Ors *et al.* 2006).

Knauth *et al.* (1997) report an investigation of 87 sports divers, none of whom had a history of DCI. Eleven (13%) showed hyperintensities on MRI, but multiple hyperintensities occurred exclusively in three subjects with large right-to-left shunts in the circulation as demonstrated by transcranial Doppler ultrasonography after the venous injection of microbubbles. Ten further subjects with similarly large shunts had normal MRI scans. Nevertheless, the possibility arises that divers with right-to-left shunts may be at particular risk of accumulating microinfarcts in the brain. The great majority of such shunts are likely to reflect a patent foramen ovale, which may well become functional only under the abnormal pressure conditions of diving. Others could be due to small atrial septal defects or pulmonary arteriovenous shunts.

Hyperostosis frontalis interna (hyperostosis cranii, metabolic craniopathy, endocraniosis, Morgagni's syndrome)

Hyperostosis of the frontal region of the skull accompanied by obesity and hypertrichosis (excessive, thick body hair) constitutes this rare syndrome. There are some indications that it may be commoner than chance expectation in patients with organic psychosyndromes.

The radiological picture is of thickening of the inner tables of the frontal bones, with smooth rounded exostoses projecting into the cranial cavity. Part of the problem in discerning any putative clinical associations lies with the frequency of the condition and with the occurrence of minor variations. It may be found at any age from adolescence upwards, increasing markedly from the third or fourth decades onwards. Females are affected very much more often than males. While the pattern of inheritance is not understood, it does occur in families and identical twin-pairs have been reported (Koller *et al.* 2005). As the bone abnormalities are so easily identified in skeletal remains, the condition has frequently been diagnosed in ancient populations, medieval and prehistoric (Hershkovitz *et al.* 1999; Glab *et al.* 2006; Mulhern *et al.* 2006; Sikanjic 2006). The pathogenesis is unknown. Two 'syndromes' have been proposed: Morgagni's syndrome, with hyperostosis, obesity and hirsutism; and Stewart–Morel syndrome, in which neuropsychiatric features predominate. Neither, however, has won wide acceptance.

In most reviews the main features have been headache, obesity, hirsutism and menstrual disorders (Capraro *et al.* 1970). Headache was found in 89% of Silinkova-Malkova and Malek's (1965/66) series compared with 37% of controls; hirsutism was present in 37% compared with 14% of controls. Thirst, water retention, sleep disturbances and a variety of rather minor endocrine changes are also described. Among mental features neurotic complaints figure prominently, also disturbances of personality, memory impairment and occasionally dementia. A number of forms of psychosis have been reported. All agree, however, that the condition is very often entirely asymptomatic.

Walinder (1977) compared a group of patients with hyperostosis frontalis interna to a matched control set and found higher rates of psychiatric morbidity in siblings of probands than in siblings of controls, suggesting a shared genetic susceptibility to psychiatric disorder only sometimes manifesting as Morgagni's syndrome.

Agensis of the corpus callosum

Absence of the corpus callosum, in whole or in part, occurs as a developmental abnormality, perhaps in as many as 1 in 4000 births (Paul *et al.* 2007). In complete agensis other associated defects may be present: hydrocephalus, microgyria, heterotopias, arachnoid cysts, spina bifida or meningocele. The anterior and hippocampal commissures may be intact even when the corpus callosum is entirely missing. Paul *et al.* (2007) provide a complete review of the known genetic causes and the underlying neurobiology.

Most cases have been reported in children, although the condition can come to light at any age. It usually presents by virtue of symptoms attributable to other cerebral malformations: seizures, mental retardation or hydrocephalus. Occasionally, however, it is discovered only at post-mortem or in

the course of neuroradiological investigations carried out for some other purpose. The discovery of asymptomatic cases is likely to increase now that brain imaging is so frequently performed.

David *et al.* (1993) and Dobyns (1996) note that complete agenesis is associated with a wide variety of genetic anomalies, including trisomies of chromosomes 8, 13 and 18. However as noted by Paul *et al.* (2007), in cases of complete, as opposed to partial, agenesis there appears to be a genetic cause in only 10–15% of cases. It appears sometimes to be the result of intrauterine metabolic disturbances such as hyperglycaemia, or intrauterine exposure to infections and toxins. Epilepsy, spasticity and other motor defects are common, likewise varying grades of mental subnormality especially in cases of partial agenesis and when associated with other conditions. However, when patients with other malformations are excluded, intelligence is usually in the normal range.

There has been a renewal of interest in the psychological status of such patients in view of the abnormal functioning known to follow surgical section of the commissures and the interest in disconnection syndromes (reviewed by David *et al.* 1993; Paul *et al.* 2007). Various cognitive deficits have been demonstrated, in particular on tests of bimanual coordination and in crossed-responding to visual stimuli and in the matching of visual patterns between left and right visual fields. However, all such deficits are variable, and other tests of interhemispheric transfer appear often to be well performed. Compensatory mechanisms must clearly be at work, by way of bilateral speech representation, increased use of ipsilateral inflow pathways, or utilisation of such other commissural pathways as are intact. Milner (1983) provides a valuable review of neuropsychological studies in such patients, concluding that while it is likely that both cognitive and skilled performances can suffer, there are clearly great individual differences from one case to another. In particular, there is no good evidence that callosal brains are less laterally specialised than normal brains, despite conflicting findings on the issue.

David *et al.* (1993) and Paul *et al.* (2007) have reviewed the association between developmental defects of the corpus callosum and major psychiatric disturbances. These have included schizophrenia, depression and behavioural disorders of childhood including overlap with autism spectrum disorders. Of the seven new cases presented by David *et al.*, four had clear psychotic symptoms, two of these being schizophrenic and one manic-depressive, one had features of Asperger's syndrome, one a personality disorder with depression and conversion symptoms, and one was an adolescent with behavioural problems. No conclusions could be drawn concerning the relevance of the callosal abnormalities to these clinical manifestations, not least because the prevalence of callosal anomalies in the general population is uncertain.

The radiological diagnosis based on the air encephalogram was first described by Bull (1967). Marked separation is

seen between the lateral ventricles; they show angular dorsal margins, concave medial borders and dilatation of the caudal portions. The third ventricle is widened with a large dorsal extension. Equivalent features can be detected on CT or MRI. Characteristic findings are seen in relation to the pericallosal arteries and other vessels on angiography.
